Glossary

coherence The state of sticking together, here meaning neurons firing (or changing firing) at the same times.

context A set of variables having to do with the environment, either internal or external.

ensembles Groups of neurons recorded simultaneously.

forebrain The rostral-most portion of the brain, including the thalamus, hypothalamus, basal ganglia, limbic system, and of course cerebral cortex.

hierarchy Classification for a system containing a series of levels, each of which does a particular job or set of jobs.

interactions Activity in one element (here, a neuron or brain region) having an impact on activity in another.

pattern completion A property of a neural network architecture, whereby the act of setting a small subset of units into a state reflecting a particular global pattern causes, through time, the rest of the network to complete this global pattern.

receptive field The range of stimuli to which a neuron responds.

taste space A theoretical organization of the relative similarities between the stimuli within a particular modality.

top-down Interregional interactions reflecting the influence of a higher level of a hierarchy on a lower level of the same hierarchy.

4.16.1 Introduction

Two main theories of taste coding, the labeled-line (LL) and across-neuron pattern (ANP) hypotheses, dominate research in gustation. The two theories are similar, in that both explain taste coding in terms of activity in populations of neurons. They differ in only one regard: according to the LL theory, a particular subgroup of neurons communicates information for a particular taste, and therefore a reduction in firing among one subgroup (say, sucrose-best neurons) codes a reduction in that taste (sweetness); according to the ANP theory, the entire population of taste-responsive neurons participates in all codes, and therefore a reduction in the response of sucrose-best neurons is expected to code both a reduction in sweetness and an increase in some other taste quality (which is coded, in part, by specifically low firing rates in sucrose-best neurons).

It is not our intent to pursue these distinctions here. Excellent pro-LL (Scott, K., 2004) and pro-ANP (Smith, D. V. and St. John, S. J., 1999) reviews have been written in the last 10 years. Instead, we will discuss a basic aspect of neural population function that is largely lacking from debates over taste coding. In this essay, we will suggest that coding in distributed neural populations is intrinsically interactive, and that future advances in our theories of gustatory population coding will therefore require an accounting of such interactions. We will present data demonstrating that such interactions occur in sensory systems, including the gustatory system. This will lead to a discussion of the spatial and temporal structures that such interactions introduce

into population activity, and finally to our suggestion that dynamic population codes may be best thought of not as coding stimuli themselves, but rather as driving the transformation of sensory-related activity into action-related activity. Guided by seminal theorizing about perception and action (Gibson, J. J., 1966; Erickson, R., 1984) and by data from taste and other sensory systems, we will argue that the time has come to think about gustatory population coding in a way that is orthogonal to the LL–ANP debate.

4.16.2 Population Coding and Neural Interactions

While the LL and ANP hypotheses both refer to activity in populations of neurons, neither suggests a specific role for interactions between the neurons. Such interactions, embodied at the simplest level by concepts such as lateral or reciprocal inhibition and excitation, would in fact introduce complications into the decoding of a LL or ANP code, because such interactions cause neural activity to be modulated through time (see below). In fact, any purely spatial coding scheme (such as both LL and ANP) proposed to function in a network in which neurons interact must include specification of the operative time period during which the spatial code will be polled for content.

By comparison, most conceptions of neural population function explicitly rely on convergence and/or feedback between nodes (see, for instance, Nagai, T. *et al.*, 1992; van Vreeswijk, C. and Sompolinsky, H., 1998; Nagai, T., 2000; Masuda, N. and Aihara, K., 2003). The earliest neural network models, founded on basic neuroscientific principles but developed before researchers had the means to do ensemble electrophysiology, suggested that population coding relies on information transfer among an entire set of neural elements (McClelland, J. L. and Rumelhart, D. E., 1981). No individual group of neurons in these models (save the input and output nodes) is profitably described as coding any particular stimulus. Instead, processing is a function of the interactions between neurons. Input to such models – even LL input – is transformed by interconnected neural networks into dynamic patterns in which individual neural elements seldom code stimulus attributes independently of their neighbors (see, for instance, Lumer, E. D. *et al.*, 1997; Rabinovich, M. I. *et al.*, 2000; Sporns, O. *et al.*, 2000).

Data collected in the light of such neural network modeling has suggested that real brain systems engage in exactly this sort of population coding. A variety of vertebrate and invertebrate sensory, cognitive, and motor systems may make explicit use of interactions between neurons (see below). These interactions introduce considerable complexity into single-neuron behavior and do processing work in neural systems. And while most of this work has been done in the visual, auditory, somatosensory, and olfactory systems, it now appears that the same can be said of the gustatory system – neuronal interactions occur both within and between brain regions in the taste neuroaxis. We will now briefly discuss those anatomical and physiological data.

Interactive processing within single brain regions can be revealed in cross-correlogram (CCG) and cross-coherence peaks, which indicate that one neuron produces action potentials in a consistent temporal relationship to those of another (Brody, C. D., 1999). When that correlated activity is specific to particular stimuli, it suggests that neural coding may involve population interactions. Such coding has been observed to occur in the somatosensory (Roy, S. and Alloway, K. D., 1999), auditory (e.g., Eggermont, J. J., 1994; DeCharms, R. C. and Merzenich, M. M., 1996; Eggermont, J. J., 2000), visual (e.g., Brosch, M. *et al.*, 1997; Lampl, I. *et al.*, 1999; Bretzner, F. *et al.*, 2001; Yoshimura, Y. *et al.*, 2005), and olfactory (e.g., Wehr, M. and Laurent, G., 1996; Christensen, T. A. *et al.*, 2003) systems, and similar findings have been reported in the frontal cortex of monkeys performing a GO NO-GO task (Vaadia, E. *et al.*, 1995) and in motor cortex (Hatsopoulos, N. G. *et al.*, 2003).

In the taste system as well, pairs of cortical neurons produce correlated spike patterns during the presentation of particular subsets of tastes (Yokota, T. *et al.*, 1996; Nakamura, T. and Ogawa, H., 1997; Yokota, T. and Satoh, T., 2001; Katz, D. B. *et al.*, 2002b). Taste administration recruits taste-specific but overlapping neuronal ensembles, including some neurons that are broadly tuned and some that according to classic single-neuron analyses cannot even be identified as taste responsive, that is, neurons with flat or unremarkable responses to taste administration may still be involved in taste-specific cross-correlations (Katz, D. B. *et al.*, 2002b). Taste-specific cross-correlations have also been observed in the nucleus of the solitary tract (NTS, Adachi, M. *et al.*, 1989) and in the pontine parabrachial nuclei (PbN, Yamada, S. *et al.*, 1990; Adachi, M., 1991). Patterns of

neural interactions appear to provide an additional source of taste-related information not inherent in single-unit spike trains, suggesting that taste neurons are embedded in interactive ensembles.

Of course, these intraregional ensembles are themselves embedded in larger interactive networks. Various dye-labeling techniques have demonstrated the existence of reciprocal connections among taste-responsive nuclei in brainstem, thalamic, limbic, and cortical regions. Just as injections of horse-radish peroxidase into PbN have revealed two parallel ascending taste pathways in rodents – a parabrachio-thalamo-cortical and parabrachio-amygdaloid pathway (Halsell, C. B., 1992) – similar methods have revealed descending pathways back to the brainstem (van der Kooy, D. *et al.*, 1984; Huang, T. *et al.*, 2003). Reciprocal connections have been shown to exist between various pairs of taste regions, including gustatory cortex (GC) and thalamus (Nakashima, M. *et al.*, 2000), GC and amygdala (McDonald, A. J. and Jackson, T. R., 1987), and amygdala and PbN (Takeuchi, Y. *et al.*, 1982). These data suggest that taste information is processed in a distributed system of information exchange involving ascending and descending pathways.

Interregional connectivity in the taste system is both convergent and functional (Di Lorenzo, P. M. and Monroe, S., 1997), just as it is in other systems (e.g., Kay, L. M. *et al.*, 1996; Alonso, J. M. *et al.*, 2001; Alloway, K. D. and Roy, S. A., 2002; Villalobos, M. E. *et al.*, 2005). For example, stimulation of GC, amygdala, or hypothalamus modifies single-neuron PbN responses to lingual application of the four basic tastes (Lundy, R. F. and Norgren, R., 2004; Li, C. S. *et al.*, 2005). A large percentage of the PbN taste neurons that receive any sort of feedback receive it from at least two forebrain sites, suggesting that multiple feedback loops may converge upon single brainstem taste neurons. Modulation of neurons in NTS, the very first central taste relay, via manipulation of both central amygdala and lateral hypothalamus, produces similar results (Cho, Y. K. *et al.*, 2003).

The specific function of feedback from forebrain to brainstem has been suggested to be a sharpening of receptive field (i.e., forebrain stimulation typically reduces the number of stimuli to which brainstem neurons respond, see Lundy, R. F. and Norgren, R., 2004). It might be tempting to conclude that the ultimately sharpened responses are evidence for a LL code, but in fact these data compellingly demonstrate that feed-forward projections are relatively broadly tuned (reflecting either broadly receptive transduction mechanisms or very early mixing of pathways), and that the apparent labeling of brainstem neurons represents an interactive network effect, in which the broad responses are tuned up by forebrain populations.

4.16.3 Functional Implications of Interactive Population Coding

The existence of interactive ensembles has strong implications for neural network function. Specifically, within- and between-region interactions affect neural activity by introducing structure – both spatial and temporal – into spontaneous and evoked neural activity. Through such imposition of structure, interneuronal interactions imbue neural activity with contextual and behavioral specificity. We will now discuss studies demonstrating that these phenomena are prominent in many neural systems and, to the extent that they have been studied, in the taste system as well.

Classical analysis of sensory neural coding relies on the tacit assumption that spontaneous, prestimulus neural activity is random and uncorrelated – noise with which stimulus-evoked signals must compete. In populations of interacting neural elements, however, spontaneous activity is far from random. Hallmark phenomena of interactive processing, such as pattern completion (Rumelhart, D. E. and McClelland, J. L., 1986), ensure that spontaneous activity can drive a network into preferred coherent states.

Little work on this topic has yet been done in the taste neuroaxis, but visual cortex has been shown to spontaneously attain spatially coherent global states (Arieli, A. *et al.*, 1996). Images of intrinsic V1 signals, keyed to the spontaneous firing of individual neurons, are nearly identical to the maps produced when those neurons' best stimuli are presented (Tsodyks, M. *et al.*, 1999; Kenet, T. *et al.*, 2003). Analogously, motor cortical networks have been suggested to attain states, referred to as preshapes, that predict population codes for particular movements well in advance of such movements (Bastian, A. *et al.*, 1998; 2003). Cortex can produce best-stimulus responses both in the presence and absence of these stimuli.

The complementary result has also been shown: cortex produces surprisingly variable responses to static stimuli. In fact, the specific spatial structure of cortical responses is less dependent on the exact

physical stimulus than on the cognitive context, that is, the animal's interpretation of the stimulus at a particular moment. In the visual system, for example, attention modulates the magnitude of sensory activity, enhancing responses to the attended object and suppressing responses to unattended ones (e.g., Fischer, B. and Boch, R., 1985; Reynolds, J. H. and Chelazzi, L., 2004). In situations in which a stimulus is bistable (e.g., the figure-ground illusion), meanwhile, cortical neurons shift firing rates in direct relation to changes in perception, despite the fact that the actual sensory stimulus is static (Leopold, D. A. and Logothetis, N. K., 1996; Otterpohl, J. R. *et al.*, 2000). Cognitive states also influence the correlations between neurons responding to simultaneously presented stimuli, modifying spatial patterns of neural interactions in cortical regions (Hatsopoulos, N. G. *et al.*, 1998; 2003), and thereby tagging the ensembles recruited to code particular real-world objects; the visual responses to disconnected line segments that are perceived to be part of a single occluded rod fire in synchrony, for instance, while responses to identical line segments that do not present the percept of an occluded rod do not (Singer, W., 1993; see also Harris, K. D., 2005).

In the taste system, as well, attentional variables affect cortical coding: when a rat ceases to pay attention to taste stimuli, the responses of 40% of the neurons in taste cortex suddenly change their receptive fields (Fontanini, A. and Katz, D. B., 2006). These changes are not random, but rather represent an interpretable modulation of perceptual taste space – specifically, an increase in the salience of the palatability dimension. Changes in orofacial responses to the tastes (Grill, H. J. and Norgren, R., 1978; Berridge, K. C., 2000) confirm this interpretation (Fontanini, A. and Katz, D. B., 2006). Such placing of coherent responses into a meaningful context has been suggested to have its source in feedback from higher neural centers (Engel, A. K. *et al.*, 2001; Buffalo, E. A. *et al.*, 2005). In other words, inclusion of multiple brain regions in the coding population places the neural code into the motivational and cognitive context, such that sensory responses reflect the meaning of stimuli, and not simply their physical makeup.

While it has not yet been shown that taste networks organize into analogous spatial coherence (but see Yoshimura, H. *et al.*, 2004), it is becoming clear that neural responses to taste administration, like those to other stimuli (e.g., Golomb, D. *et al.*, 1994; Vaadia, E. *et al.*, 1995; MacLeod, K, and Laurent, G., 1996; Seidemann, E. *et al.*, 1996; Compte, A. *et al.*, 2000; Kirkland, K. L. *et al.*, 2000; Bazhenov, M. *et al.*, 2001; Miller, P. *et al.*, 2005), do have temporal structure. Such temporal structure has been extensively described in both brainstem (Di Lorenzo, P. M. and Schwartzbaum, J. S., 1982; Erickson, R. P. *et al.*, 1994; Di Lorenzo, P. M. and Victor, J. D., 2003) and cortex (Katz, D. B. *et al.*, 2001; see also Tabuchi, E. *et al.*, 2002). The use of chronic recordings in active, tasting rats has allowed us to observe not only slower dynamics but also oscillations (Fontanini, A. and Katz, D. B., 2005) in taste cortex, a region rife with inhibitory cross-talk (Ogawa, H. *et al.*, 1998). These cortical dynamics have been directly linked to network functioning (Katz, D. B. *et al.*, 2002b), a finding that is consistent with paired-pulse studies showing that two identical inputs, separated by just long enough to allow the processing of information from the first input to begin, cause reliably distinct patterns of response in NTS neurons (Lemon, C. H. and Di Lorenzo, P. M., 2002; Di Lorenzo, P. M. *et al.*, 2003). Gustatory responses are clearly dynamic, as predicted by interactive population models (but not by either the LL or ANP model).

Analogous to the above findings on spatial coherence, perceptual relevance emerges in the temporal structure of cortical taste responses, much as it does in other systems (Sugase, Y. *et al.*, 1999; Friedrich, R. W. and Laurent, G., 2001). While data from primates have suggested that only prefrontal cortical activity is affected by important changes in state (i.e., satiety, Rolls, E. T. *et al.*, 1989), rat primary cortical responses clearly contain both sensory and cognitive components. These responses can be divided in three epochs, each of which reflects a particular stage of gustatory processing – somatosensation, chemosensation, and palatability (Katz, D. B. *et al.*, 2001). Attention-related changes in stimulus palatability are preferentially expressed in changes in late-epoch coding (Fontanini, A. and Katz, D. B., 2006), a fact that reinforces the conclusion that the three epochs represent genuine temporal coding, rather than trivially reflecting the outcome of processing.

The evolution of activity during these three epochs could be the result of interactions/reverberations between the gustatory system and other high-order areas known to code palatability, such as the amygdala (Nishijo, H. *et al.*, 1998). It has also recently been shown that even later aspects of cortical responses in rats change as a taste becomes familiar (Bahar, A. S. *et al.*, 2004). Thus, cognitive processes are apparent both in the spatial and temporal

structures of sensory responses, as one expects when examining a system functioning via interacting populations of neurons.

4.16.4 The Purposes of Neural Interactions in Taste

It is clear that the behavior of neurons in primary GC must be interpreted in terms of context – both the physical context of the networks (of neurons and brain areas) into which the neuron is connected and the cognitive context of the task. Primary GC is not a passive receiver, but rather a dynamic processor of information constantly engaged in a behaviorally dependent interplay with other regions; taste neurons in cortex interact with populations of neurons throughout the taste neuroaxis in the process of stimulus coding. A fundamental issue that remains to be addressed, however, is the definition of the term coding. Put another way, the question is: what kind of processes are interacting populations of taste neurons involved in?

It has been suggested that neural ensembles may interact for the purposes of binding and/or effective signal transmission, collapsing neurons into a functional, synchronous ensemble in order that this ensemble may code a context-embedded percept. Intraregional connectivity is thought to allow flexible assembly of a broad range of possible ensembles, while longer-range connections modulate that assembly according to global (cognitive) states (Brosch, M. *et al.*, 1997). This hypothesis has been further extended to consider time-varying responses, wherein distinct subpopulations of neurons fire synchronously at different times during the response (Vaadia, E. *et al.*, 1995; Wehr, M. and Laurent, G., 1996).

Synchrony is potentially powerful, because synchronous input can be decoded by coincidence-detecting readout cells whose firing represents a synthetic and sparsened version of the input. Perhaps the most well-studied example comes from the insect olfactory system. Kenyon cells in the mushroom body of the locust and fly receive complex, time-varying inputs from populations of projecting neurons in the antenna lobe (Laurent, G. *et al.*, 2001; Lei, H. *et al.*, 2004; Wilson, R. I. *et al.*, 2004) and respond to this very complex input with relatively few – and very reliable – action potentials following the arrival of synchronous inputs (Perez-Orive, J. *et al.*, 2002). The attractiveness of the synchronization hypothesis lies in the ease with which it fits into an overall vision of the brain as a coding–decoding device: every area codes the input according to some rules and feeds its output to a higher level area that synthesizes it into a sparser representation. In this framework the brain is treated as a linear hierarchical system, where the output of a level is sent to the next, and where the highest level decodes a fully contextualized percept.

The evidence collected thus far, however, does not provide strong support for such a model of gustatory function. As described above, information traversing the gustatory system is hierarchical only to a first approximation – for every ascending pathway between brainstem and forebrain there is matching feedback. In the context of this recurrent organization it is hard to identify the putative decoding zone in which convergence and sparsening might occur. Recordings confirm that the taste selectivity of neural responses does not increase by a great deal as one ascends through the system (Yamamoto, T. *et al.*, 1985; Ogawa, H. *et al.*, 1990; Nishijo, H. *et al.*, 1998), and there is not much evidence for synchrony or oscillations during gustatory processing. In fact, while oscillations occur prominently in gustatory cortex, they specifically occur when rats are not engaged in taste processing (Fontanini, A. and Katz, D. B., 2005). Significant CCGs between pairs of neurons separated by more than 100 μm, meanwhile, appear to reflect simultaneous changes of firing rate, rather than synchronous firing of action potentials (Katz, D. B. *et al.*, 2002b).

Alternative theories avoid the coding–decoding issue entirely, simply by suggesting that processing of a sensory stimulus can be accomplished in the absence of coding of the sensory stimulus. Several researchers and philosophers (see, for instance, Varela, F. J. *et al.*, 1991; van Gelder, T., 1992; Eggermont, J. J., 1998; Engel, A. K. *et al.*, 2001), including more than one chemosensory scientist (Freeman, W. J. and Skarda, C. A., 1994; Halpern, B. P., 2000), have suggested that coding and representation may be constructs with more relevance to computer function than to brain function. Such a notion is *prima facie* attractive, because all extant concepts of taste coding run into trouble over the fact of the wide range of response latencies produced in gustatory behavior – the fact that some taste responses can be produced as little as 200 ms following taste administration, while others take well over 1 s (Halpern, B. P., 2005). Furthermore, it makes sense from an ecological prospective, in that the function of gustation is to provide information for

the crucial decision of ingesting or rejecting food (Gibson, J. J., 1966). Taste is therefore intimately linked to orofacial motor behavior – a linkage that is explicit in the fact that the brainstem taste relays are almost directly connected into orofacial motor-neuron pools (Travers, J. B. and Norgren, R., 1983; Travers, J. B. *et al.*, 2000). It may be reasonably argued that the job of populations of neurons in the gustatory neuroaxis is not to code tastes at all, but rather to transform taste input into motor output. In such a scheme, the spatial hierarchy in which each successive brain region contains more highly processed information is replaced by a temporal hierarchy in which successive time points contain more highly processed information.

This, then, would be the function of interacting neural populations – to transform input, through poststimulus time, into a form adequate for driving behavior. Stimulus-related input does not get represented by neural firing (or even by neural synchrony) for any particular finite time, but rather sets in motion a dynamic process of population interaction (Harris, K. D., 2005). This is consistent not only with the recent data on temporal coding and cross-correlations in taste (Katz, D. B. *et al.*, 2002a), but also with data from other systems showing: (1) action-oriented responses in early sensory relays (Kay, L. M. and Laurent, G., 1999, Shuler, M. G. and Bear, M. F., 2006); (2) emergence of perceptual information through time (Sugase, Y. *et al.*, 1999); and (3) intriguing new data suggesting that visual input merely perturbs active processes already underway in V1 (Fiser, J. *et al.*, 2004).

4.16.5 Conclusions

These are necessarily speculative musings, because the study of interactive population coding in taste cortex and the larger taste neuroaxis is still in its infancy. We do not write this review in an attempt to resolve the debate between LL and ANP theories – both theories have their adherents, both can be thought to receive support from data, and as of now neither can be disproved in the central nervous system. Our suggestion is that we will need a more explicit account of interacting populations, perhaps adapted from research in other systems, if we are to provide the necessary framework for a complete understanding of the functioning of taste networks. These interactions exist in the taste system, as they do in other, more extensively examined systems and in realistic neural models. The extant theory and data suggest that they may be central to sensory function – function that may conceivably have more to do with transforming input smoothly into motor output than with actual coding of the stimulus *per se*. It will likely be years before these issues can be completely resolved.

Glossary

Dedicated sensory neurons They are activated by single or multiple chemosensory receptors to directly and separately code each chemosensory quality.

Discrete stimuli They are separate entities that may share parts and sizes. Chemosensory stimuli are examples; each chemosensory receptor has a discrete molecular domain.

Dynamic chemosensory coding It promotes brief identification of the strong and novel in a complex chemical mixture by combining mixture suppression and rapid sensory adaptation.

Hedonic valence It is positive when a chemosensory stimulus is perceived as good; negative when a chemosensory stimulus is perceived as bad.

Odor notes They are distinct perceptual olfactory qualities; there are hundreds, grouped as object-like (e.g., flower, fruit, animal) or process-like (e.g., spoiled, excreted, burned).

Perceptual continua They are constructed for color and pitch by red-green and blue-yellow opponent cells for each retinal position and multicell frequency maps, respectively.

Quality constancy This occurs if a chemosensory quality remains the same in different contexts, allowing chemosensory stimulus recognition.

Quality tuning They may be broad or fine, depending on how stimuli are biologically detected and species-selective perceptual requirements. An example of broad tuning is the tripartite cellular code for color carried by three pigments, each found in a dedicated retinal cone. An example of fine receptor tuning is the best-frequency cellular code for pitch carried by hundreds of cochlear hair cells.

Somatotopic neural maps These represent distinct touch, pain, warm, and cold senses side by side for each bodily place: for example, on legs, arms, head, nose, mouth, and tongue.

Sound space This is coded in interaural time differences but visual space is coded by positions in images projected on the retina.

Spectral stimuli They are continuous and unidimensional; examples are the visible spectrum of electromagnetic waves and the audible spectrum of airborne pressure waves.

Taste qualities They are distinct perceptual gustatory qualities; there are few; primarily sweet, salty, sour, and bitter.

4.17.1 The Sweet–Salty–Sour–Bitter Decision

In humans, the essence of most tastes is described by a handful of distinct qualities. There are hundreds of odor qualities. The logic of chemosensory coding must take into account the hundreds of different olfactory receptors (ORs) (Axel, R., 2005; Buck, L. B., 2005) compared to the many fewer receptors implicated in taste reception (Chandrashekar, J. *et al.*, 2006), both of which are now being characterized for a multiple mammalian species.

For tastes, besides quality, that is, the sweet–salty–sour–bitter decision, there is a good–bad decision (Nowlis, G. H. and Frank, M. E., 1981), as there is for smells (Anderson, A. K. *et al.*, 2003). The gustatory and olfactory systems code hedonic attributes that are associated with the water-soluble and airborne chemicals that they, respectively, detect. The good–bad decision about tastes and smells can be changed with experience (Cain, W. S. and Johnson, F., 1978; Palmerino, C. C. *et al.*, 1980). In contrast, the sweet–salty–sour–bitter and odor note decision, although it may be enhanced or dulled via intensity shifts (Contreras, R. J. and Lundy, R. F. 2000), appears unchanged and recoverable. The neural basis for sweet–salty–sour–bitter decisions, like odor-quality decisions, persists intact throughout the brain. This is consistent with taste-quality (Frank, M. E. *et al.*, 2003) and odor-quality (Goyert, H. F. *et al.*, 2007) constancy. The constancies are necessary and sufficient for chemosensory stimulus recognition, and instruct us on the logic of chemosensory coding in the central nervous system (CNS).

4.17.2 Stimulus and Perceptual Domains

It would simplify the study of sensory systems if all systems detected stimuli and coded perceptions in one way (Erickson, R. P., 1985). However, by their nature, different kinds of stimuli do not fall along comparable stimulus dimensions (Frank, M. E. and Hettinger, T. P., 2005). It may be convenient to use well-studied senses such as visual color or auditory pitch as model systems, but is it productive? Color and pitch are spectral senses in which stimuli fall on convenient physical continua that can be sampled with a frequency sweep. Sampling chemosensory stimuli, in contrast, is discrete; there is no single stimulus dimension to sweep across.

4.17.2.1 Nonchemosensory

4.17.2.1.1 Pitch

Pitches, like tastes and smells, neither define external space, like color, nor identify stimulation sites, like the somatotopic body senses. The stimulus domain of pitch is temporal, a spectrum of molecular pressure waves. In the cochlea, these waves are transformed to a cellular continuum. The waves localize according to frequency from the apex to the base of the basilar membrane (Békésy, G. von, 1970). Pitch is detected mechanically by multiple individual receptor cells (inner hair cells) located at multiple points along the vibrating membrane. The activated cells create a neuronal continuum in cranial nerve (CN) VIII that is transmitted to the neurons in the brainstem cochlear nucleus. CN VIII fibers mostly connect one to one to inner hair cells, a connectivity that sets the fibers' quite specific best-frequency tuning (Goldstein, E. B., 2007). This is fine tuning.

Thus, a temporal stimulus domain is translated into an intercellular domain to code pitch in the auditory nerve. In the CNS, frequency is mapped multiple times from cochlear nucleus to auditory cortex, and, as a consequence, pitch information is present in the form of maps everywhere in the auditory CNS. Taste quality information is also found throughout the gustatory CNS but does not appear to be in the form of sweet–salty–sour–bitter maps; rather, tastes and other oral senses originating from the same regions may be aligned (Chapter 4.15; McPheeters, M. *et al.*, 1990; Lundy, R. F. and Norgren, R., 2004; Kaas, J. H., 2005). Odor-quality signals detected by the subsets of olfactory sensory neurons (OSNs), each exclusively expressing a single OR variant, converge onto a few particular glomeruli in the olfactory bulb; but this stereotyped OR-based representation is neither somatotopic nor recapitulated elsewhere in the brain (Buck, L. B., 2005).

4.17.2.1.2 Color

The most popular model used to instruct studies of chemosensory systems is color vision (Erickson, R. P., 1985; Shepherd, G. M., 2005). Colors are parts of every discrete spot of every image in the visual field. In that sense, color, unlike pitch, is a spectral percept distributed in external space. Color stimuli are electromagnetic waves within a continuous visible spectrum and spectral sensitivity

is species-dependent (Glosmann, M. and Anhelt, P. K., 2002). The continuum of visible frequencies is partitioned by a few chemical pigment chromophores. In humans each chromophore is located exclusively in one of the three subsets of cone receptor cells in the retina. The three human cones contain all our color information. Each cone pigment absorbs light across the entire visible spectrum, with absorbance peaking at different frequencies. This is a broad tuning, characteristic of pigment absorbance.

Thus, a visible spectral wavelength continuum is reduced to a tripartite cellular code present in separate cells: so-called red (L), green (M), and blue (S) cones. Within the retina, the three cone spectra are combined to yield blue-yellow (L + M) and red-green opponent retinal ganglion cells associated with every spot on the retina, and these two opponents are represented in neurons distributed throughout the visual system from thalamus to visual cortex (Goldstein, E. B., 2007). Exactly how the continuity of colors that we perceive localized to each spot in our visual experience is reconstructed from absorbance differences of several pigments by the brain is unknown (Lennie, P., 2000). In the gustatory system there are peripheral and central neurons that respond antagonistically to good–bad stimulus pairs. (Chapter 4.15; McPheeters, M. *et al.*, 1990; Formaker, B. K. *et al.*, 1997).

4.17.2.2 Chemosensory

In contrast to the spectral senses of color and pitch, chemosensory stimulus detection in mammals involves discrete stimulus–receptor biochemical interactions, reactions with specified chemosensory molecular ranges (Bargman, C. L., 2006). Not needing to first convert spectral information to chemical or mechanical information in order to activate cells, the chemical senses coding logic can be more direct and represents phyletically early sensing systems. Candidate G protein-coupled receptors (GPCRs) have been discovered for (1) sweet taste; (2) mostly unidentified, species-specific, bitter tastes (Chandrashekar, J., *et al.*, 2006); and (3) multiple, mostly unidentified, species-specific odors (Axel, R., 2005; Buck, L. B., 2005). In nearly all the cases, the environmental ligands that match the receptors are unknown.

4.17.2.2.1 Taste

The perceptual simplicity of taste has facilitated the identification of a single heterodimeric GPCR taste receptor (TR) for sweet compounds (Tas1r2–Tas1r3), which has a molecular range coincident with compounds that taste sweet to humans (Li, X. *et al.*, 2002). The molecular range is species-selective. Tas1r2 is not expressed in cats (Li, X. *et al.*, 2005) and, consequently, cats do not detect sweet stimuli. Just as each OR is expressed in a dedicated set of OSNs, the single sweet TR is found in a subset of taste receptor cells (TRCs) likely dedicated for signaling sweet stimuli (Chandrashekar, J. *et al.*, 2006).

An alternate arrangement has been implicated for bitter taste. Multiple candidate bitter receptors have been discovered, but all 30 T2Rs may be expressed in each cell of a subset of TRCs. Similar arrangements have been seen for nematode chemosensory receptors (Bargman, C. L., 2006). Each T2R receptor of a given species would detect distinct dangerous chemicals, possibly produced by other competing species. (Hettinger, T. P. *et al.*, 2007). In contrast to sweet, no single TR could service the chemical diversity of bitters with appropriate specificity. However, this tentative bitter coding logic fails to account for the fact that all bitter stimuli do not necessarily elicit a unitary sensation. Rodent chorda tympani and glossopharyngeal nerves, both of which may innervate TRCs containing T2Rs, carry distinct information about aversive stimuli to the brain (St. John, S. J. and Spector, A. C., 1998; King, C. T. *et al.*, 2000) and code for several distinct aversive perceptions (Frank, M. E. *et al.*, 2004; Hettinger, T. P. *et al.*, 2007) that have perhaps been reduced to a single bitter in humans.

4.17.2.2.2 Smell

In comparison to TRCs, identification of the function of particular dedicated OSNs has been a struggle, likely for the same reason that odor qualities have not been satisfactorily classified (Cain, W. S., 1978): there are so many odors and many may be sensed only by a few related species (Niimura, Y. and Nei, M., 2006). Just like tastes, odors are not distinguished merely as feature detectors of stimulus functional groups, shapes, or sizes. Rather, TRs and ORs likely evolved to make distinctions among particular whole molecules important for survival, some sharing functional groups, and with as much specificity as required for recognition (Bargman, C. L., 2006; Mori, T. *et al.*, 2006; Goyert, H. F. *et al.*, 2007).

Thus, like the body senses (McBurney, D. H. and Gent, J. F., 1979), there is a distinctly possible direct coupling of TR or OR with a discrete chemosensory quality, taste, or odor. Deconstruction of stimulus

dimensions and their reconstruction into perceptual dimensions by the brain (Buck, L. B., 2005) may be appropriate for continuous spectral senses partitioned by a few receptor cell types like color. However, deconstruction and subsequent reconstruction (Turin, L., 2006) may be unnecessary for multiple discrete chemosensory domains.

4.17.3 Processing of Chemosensory Quality Signals

Although processing can potentially occur among the TRCs within taste buds (Kaya, N. *et al.*, 2004; Roper, S. D., 2006), recent findings strongly suggest that perceptual taste categories are isomorphic with TR specificity (Chandrashekar, J. *et al.*, 2006). This is consistent with modular specificities defined by single taste-fiber neural responses transmitted to the CNS (Frank, M. E., 2000; Frank, M. E. *et al.*, 2005).

4.17.3.1 Mixtures

Sweet–salty–sour–bitter is a set of distinct taste perceptions that is not transformed in stimulus mixtures (Frank, M. E. *et al.*, 2003). Figure 1 demonstrates this with the specificity of intake suppression driven by conditioned taste aversions, which do not alter the sweet–salty–sour–bitter decision (Hettinger, T. P. *et al.*, 2007). The taste of NaCl is recognized by hamsters in the binary mixtures of NaCl and sucrose, or NaCl and quinine, or the ternary mixture of NaCl and sucrose and quinine. The mixture percepts contain salt-like components. There are specific adjustments in intensity, however. One example is the suppression of quinine recognition in the presence of NaCl (Figure 1); but it can be recovered by an increase in quinine concentration (Nowlis, G. H. and Frank, M. E., 1981). There is also a mixture suppression of intensity in ternary mixtures (e.g., sucrose results in Figure 1). Mixture suppression, seen in humans (Bartoshuk, L. M., 1975), focuses mixture perception on the stronger mixture components.

In taste, mixture processing begins in the taste bud (Formaker, B. K. *et al.*, 1997), perhaps between the multiple TRCs containing cells expressing receptors for distinct qualities, and may continue within the brainstem nucleus of the solitary tract, which, like the olfactory bulb, contains ample inhibitory interneurons within its circuitry (Chapter 4.15; Bradley, R. M., 2006). In chemosensory mixtures, stronger stimuli suppress the weaker one more than the weaker

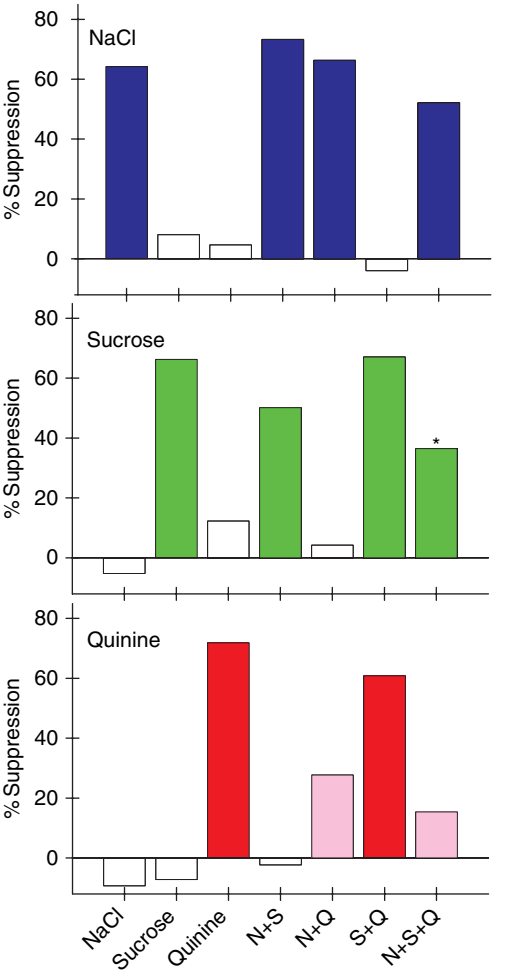

Figure 1 Recognition of components of binary and ternary taste mixtures by hamsters. The percentage suppression of intake measures stimulus recognition. NaCl (100 mM) was recognized (blue bars) in mixtures containing NaCl (N). Sucrose (100 mM) was recognized (green bars) in mixtures containing sucrose (S). Quinine (1 mM, Q) was recognized (red bars) in sucrose–quinine mixtures but not in NaCl–quinine mixtures (pink bars). *Sucrose recognition was weaker for the ternary S+N+Q mixture than for sucrose alone. Data are from Frank, M. E., Formaker, B. K., and Hettinger, T. P. 2003. Taste responses to mixtures: analytic processing of taste quality. Behav. Neurosci. 117, 228–235.

suppress the stronger (Laing, D. G. *et al.*, 1984). In this context, there is also an important temporal process to consider, rapid sensory adaptation.

4.17.3.2 Chemosensory Quality Constancy

Quality tuning of brainstem and forebrain taste neurons appear, on average, to broaden when compared

to tuning of receptors or taste nerve fibers (Chapter 4.15). Explanations of how tuning profiles change at different levels of the nervous system should lead to a greater understanding of the roles of identified CNS neurons with distinct inputs and projections (Bradley, R. M., 2006). Likely some CNS transformations serve to stabilize a compound's taste or odor quality in a complex labile chemical environment. Stimuli that we usually experience are not pure or equally strong but are combinations of multiple compounds that wax and wane in time. In both taste and smell, identification of mixture components falls off rapidly with decreases in intensity and with increases in the number of components (Laing, D. H. *et al.*, 1984; Livermore, A. and Laing, D. H. 1998; Laing, D. H. *et al.*, 2002). In odor mixtures, rapid adaptation and mixture suppression determine which characteristic odors will be identified at a given moment (Goyert, H. F. *et al.*, 2007). Unlike taste for which taste buds are potential sites of TRC interaction, OSN interactions are initiated in the complex layered olfactory bulb via well-defined inhibitory circuitry (Yokoi, M. *et al.*, 1995) before they are transmitted to higher central levels.

Figure 2 shows correct identification of four characteristic odors by people. Each odor is recognized more often if other mixture components are sniffed for a few seconds right before (solid color bars) and less often if the test component itself is sniffed right before (diagonal striped bars). Instead of cross-adapting, the other odors release mixture suppression among the signals for the four compounds. For example, the odor of vanillin, labeled vanilla, is recognized more frequently in two-, three-, and four-component mixtures when the other mixture components, isopropyl alcohol, menthol (labeled mint), and phenethyl alcohol (labeled rose), are sniffed first. Vanillin recognition is poorer after it is sampled. The dynamic coding mechanisms of mixture suppression and rapid adaptation promote recognition of characteristic odors of newly introduced and stronger chemosensory stimuli. Chemosensory circuits may have evolved to focus our attention on the recognition of chemicals that we need to know are there in the environment or the mouth: serious new opportunities for, or dangers to, our survival.

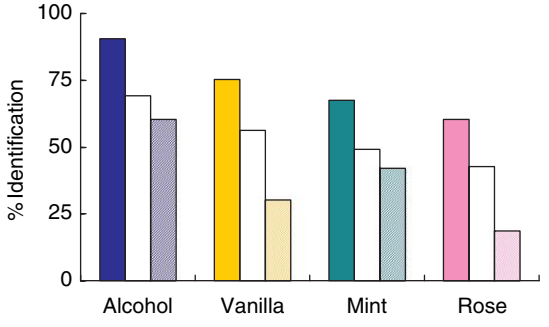

Figure 2 Identification of components in two-, three-, and four-component mixtures. The stimuli (labels) were 1 M isopropyl alcohol (alcohol), 5 mM vanillin (vanilla), 1 mM *l*-menthol (mint), and 0.5 mM phenethyl alcohol (rose). Correct component identification was greatest following sniffing other mixture components (solid color bars) for a few seconds and poorest following sniffing stimuli containing the indicated component (striped color bars). White bars are controls. Data are from Goyert, H. F., Frank, M. E., Gent, J. F., and Hettinger, T. P. 2007. Characteristic component odors emerge from mixtures after selective adaptation. Brain Res. Bull. 72, 1–9.

4.17.4 Conclusion

Stimuli that we usually encounter are not pure chemicals but combinations of varying amounts of multiple compounds that come and go. In such shifting contexts, a few taste or odor qualities are identified at a time. This dynamic chemosensory coding (Goyert, H. F. *et al.*, 2007) warrants further study in peripheral taste neurons, which transmit signals to the CNS after they are processed by taste buds, and in mitral and tufted cells, which transmit the processed signals from the olfactory bulb to the olfactory cortex. The taste or odor perceived is typically characteristic of the pure component, a chemosensory quality constancy: the objective of quality coding. The Pied Beauty described in G. M. Hopkins' poem (Nowlis, G. H. and Frank, M. E., 1981) for chemosensory perceptions may not be appreciated all at once, except in our memories.

Glossary

adaptation Reduction in the response magnitude of a sensory neuron during a maintained stimulus.

chemesthesis Sensations of a burning, stinging, tingling, or anesthetic quality elicited by chemical stimulation of the mucosa or skin.

desensitization (tachyphylaxis) Reduction in response to reapplication of a stimulus. Self-desensitization refers to a reduced response to reapplication of the same stimulus, and cross-desensitization is a reduction in the expected magnitude of a response to one stimulus when preceded by a different conditioning stimulus.

masking Inability or reduced ability to detect a stimulus in the presence of another stimulus, usually of a higher intensity.

nociceptor Sensory receptor innervating skin, mucosa, or other tissues that respond to noxious (potentially or overtly damaging) stimulation.

noxious Of sufficient intensity to threaten or overtly damage tissue.

pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

sensitization Progressive increase in perceived sensory intensity during repeated application of a fixed stimulus (also refers to increased response of a sensory neuron following a noxious conditioning stimulus).

stimulus-induced recovery After desensitization, repeated reapplication of the stimulus induces a progressive increase in response that eventually reaches the same level as before desensitization.

TRP Transient receptor potential class of ion channels, some of which respond to chemicals or temperature changes.

Oral somatosensation provides important information regarding the texture, temperature, and pungency associated with oral stimuli. These stimuli are detected, respectively, by the presence of mechanosensitive, thermosensitive, and nociceptive neurons that are dispersed throughout the oral epithelium (Nagy, J. I. *et al.*, 1982; Whitehead, M. C. and Frank, M. E., 1983; Ito, J. and Oyagi, S., 1995). Whereas mechanosensitive neurons have receptor endings specialized to detect specific mechanically evoked sensations (e.g., vibration), thermosensitive neurons and nociceptors are thinly (Aδ-fibers) or unmyelineated (C-fibers) and are believed to have free nerve endings that respond to non-noxious heat and cold or various types of noxious stimuli including those of thermal, mechanical, or chemical origin (Dubner, R. and Bennett, G. J., 1983; Sessle, B. J., 1987; Willis, W. D. and Westlund, K. N., 1997; Millan, M. J., 1999). Although nociceptors are specifically tuned to convey sensations of pain, it is currently unclear whether

nociceptors responsive to a particular class of noxious stimuli exist (e.g., chemonociceptors) (Schmidt, R. *et al.*, 1995). Sensitivity to chemical irritants serves to protect organisms against exposure to potentially harmful compounds. This specialized sense, defined in the early 1900s (Parker, G. H., 1912) as the common chemical sense, is mediated by chemonociceptive nerve fibers and is separate from the system that provides chemosensitivty to taste and smell molecules (although at high concentrations, salts and acids can evoke sensations of pain; Carstens, E. *et al.*, 1998; Dessirier, J. M. *et al.*, 2000a; 2001b). More recently, objections to the term common chemical sense has resulted in the term chemesthesis being used to describe the sensations resulting from chemical activation of somatosensory pathways (Green, B. G. *et al.*, 1990). Chemesthesis refers to the ability to detect and respond to potentially noxious chemical stimuli across the entire body, not just in the oral or nasal mucosa. Whereas mucosal membranes (such as the cornea and oral and nasal epithelium) are generally more sensitive to chemical irritants, the mechanisms that subserve the detection of noxious chemicals are likely the same as those occurring in skin. The important feature which differentiates oral chemesthesis from generalized chemesthesis relates to its contribution to flavor. The pungency associated with horseradish, the burn of hot chili peppers, and the tingle induced by carbonated beverages all result from the activation of neural pathways sensitive to specific chemicals. In fact, along with taste and smell, oral chemesthesis is often considered to be one of the three main contributors to food and beverage flavor profiles. As such, increasing attention has been paid to oral chemesthesis and its impact on taste and flavor perception.

4.18.1 Oral Chemesthesis: Anatomy

The detection of oral irritants is achieved primarily by the activation of the trigeminal nerve, although the glossopharyngeal and vagus nerves also participate (Figure 1). The trigeminal nerve, as the name suggests, is comprised of three divisions that innervate the whole of the orofacial region. The mandibular and maxillary divisions are responsible for conveying somatosensory information from the oral cavity, whereas the ophthalmic division, via the ciliary and ethmoid nerves, innervates the cornea and nasal epithelium, respectively. The mandibular branch is the largest of the three divisions and innervates the anterior tongue and mandibular dental pulp. Unlike the maxillary and ophthalmic divisions, the mandibular division is a mixed nerve and contains both afferent and efferent fibers (Shankland, W. E., 2001b). Of particular importance for detecting oral irritants, trigeminal innervation of the anterior tongue occurs via the lingual nerve (Sostman, A. L. and Simon, S. A., 1991; Wang, Y. *et al.*, 1993). Although nociceptive fibers are found across the entire lingual surface, they terminate most densely in close proximity to taste buds (Nagy, J. I. *et al.*, 1982; Finger, T., 1986; Whitehead, M. C. and Kachele, D. L., 1994; Whitehead, M. C. *et al.*, 1999). This so-called perigemmal pattern of innervation is different from that of gustatory fibers which make intragemmal (within taste bud) synaptic contact with taste receptor cells. The midfacial region is innervated by the maxillary division of the trigeminal nerve. The maxillary division is a sensory nerve comprised exclusively of afferent fibers (Shankland, W. E., 2001a). The maxillary branch innervates many important structures for the detection of oral irritants including the soft and hard palate, the tonsils, and the nasopharyngeal mucosa (Shankland, W. E., 2001a). Although not involved in oral chemesthesis, the ophthalmic division of the trigeminal nerve is important in nasal irritation (Silver, W. L. and Moulton, D. G., 1982). The ethmoid nerve conveys afferent signals from the nasal mucosa, and sensitivity to nasal irritants has been linked to sick-building syndrome (Shusterman, D., 2003) and other disorders including seasonal allergic rhinitis (Shusterman, D., 2002).

In addition to the trigeminal nerve, the glossopharyngeal and vagus nerves also contribute to oral chemosensitivity by responding to oral irritants, as well as tastants, delivered to the posterior oral cavity. Specifically, the glossopharyngeal nerve responds to chemoirritants delivered to the posterior tongue (Barry, M. A. *et al.*, 1993; Hayakawa, T. *et al.*, 2005) as well as the soft palate (Hayakawa, T. *et al.*, 2005) and upper oropharynx (Hayakawa, T. *et al.*, 2005). The vagus nerve is activated by irritants delivered to the lower pharynx and the epiglottis (Boucher, Y. *et al.*, 2003).

Primary afferent somatosensory fibers from the oral cavity and throat project, in a topographical manner, to central relays in the brainstem. Trigeminal afferents carry information to the brainstem trigeminal complex where there appears to be some segregation in the processing of different types of somatosensory inputs. Nociceptive and thermally sensitive fibers project to superficial layers (I–II) of

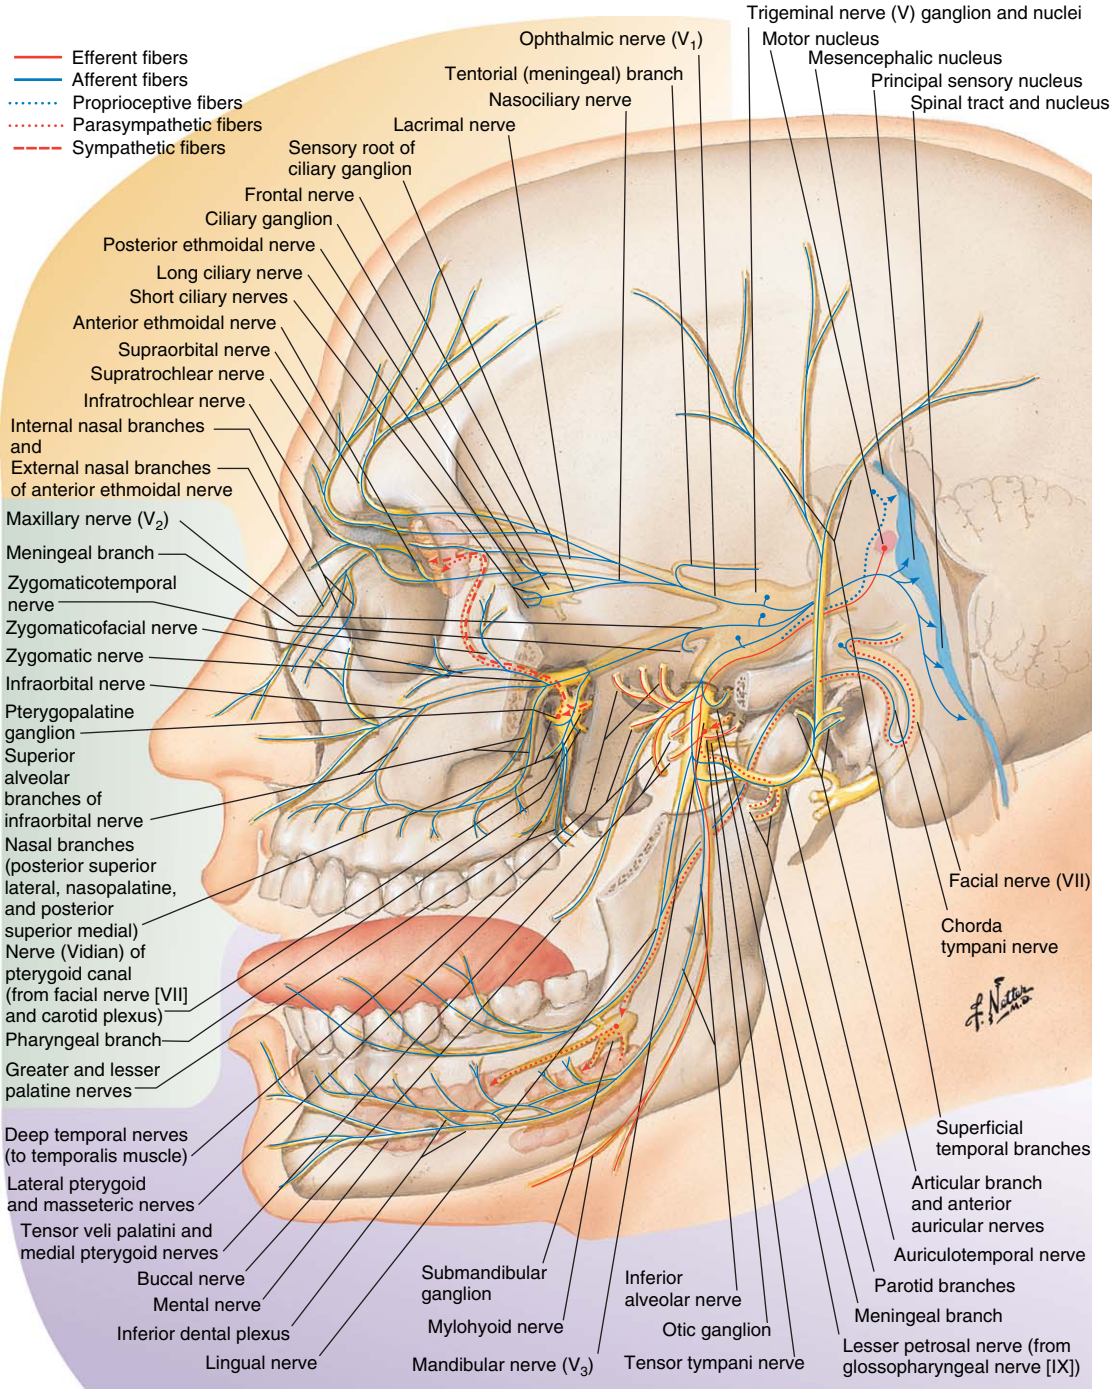

Figure 1 Anatomy of the trigeminal nerve, its innervation territory, and central connections. From Netter, with permission.

the trigeminal complex, whereas innocuous low-threshold mechanical stimuli activate neurons in superficial as well as deeper (III–IV) trigeminal layers (Hu, J. W. *et al.*, 2005). As the majority of studies investigating oral chemesthesis have focused on lingual sensitivity, more is known regarding the topographical organization of lingual inputs compared to other nerve inputs (however, see Rentmeister-Bryant, H. and Green, B. G. 1997; Green, B. G. 1998). In particular, it has been shown

that lingual nociceptors project to the superficial layers of the trigeminal subnucleus caudalis (Vc) (Hayashi, H., 1985; Jacquin, M. F. *et al.*, 1986; Komai, M. and Bryant, B. P., 1993; Strassman, A. M. and Vos, B. P., 1993; Coimbra, F. and Coimbra, A., 1994). There they form synaptic connections with second-order neurons involved in relaying nociceptive information to higher centers (Kruger, L. and Michel, F., 1962; Yokota, T., 1975; Amano, N. *et al.*, 1986; Strassman, A. M. and Vos, B. P., 1993; Carstens, E. *et al.*, 1995; Raboisson, P. *et al.*, 1995; Carstens, E. *et al.*, 1998; Simons, C. T. *et al.*, 1999; Dessirier, J. M. *et al.*, 2000b; Simons, C. T. *et al.*, 2000; Carstens, E. *et al.*, 2002a). Although Vc has been the most extensively studied (for review see Sessle, B. J. and Greenwood, L. F., 1976; Hu, J. W. *et al.*, 1981; Dubner, R. and Bennett, G. J., 1983), the more rostral trigeminal subnuclei interpolaris and oralis are also involved with processing and relaying oral pain information (Greenwood, L. F. and Sessle, B. J., 1976; Sessle, B. J. and Greenwood, 1976; Nord, S. G. and Young, R. F., 1979; Hu, J. W. *et al.*, 1981; Hayashi, H. *et al.*, 1984; Hu, J. W. and Sessle, B. J., 1984; Hayashi, H. and Tabata, T., 1989; Dallel, R. *et al.*, 1990; Jacquin, M. F. and Rhoades, R. W., 1990; Raboisson, P. *et al.*, 1991; Hu, J. W. *et al.*, 1992; Ohya, A., 1992; Ohya, A. *et al.*, 1993; Dallel, R. *et al.*, 1996).

Oral somatosensory information conveyed by non-trigeminal nerve fibers also project topographically to brainstem nuclei. Both, the glossopharyneal nerve and the vagus nerve project to the nucleus of the solitary tract (NTS). *c-fos* studies of nicotine-induced throat irritation have shown that vagal afferents project to the most caudal aspects of the NTS (Boucher, Y. *et al.*, 2003). The glossopharyngeal nerve, on the other hand, projects more rostrally (Hamilton, R. B. and Norgren, R., 1984). Importantly, although both nerves encode the quality and intensity of oral somatosensory and taste stimuli, the processing of such information is segregated and distributed to different parts of the NTS. Taste processing occurs in rostral medial NTS, whereas somatosensory processing occurs more laterally (Barry, M. A. *et al.*, 1993). Interestingly, collateral branches from trigeminal afferents also project to rostromedial NTS, providing a substrate by which trigeminal–taste interactions might occur (Jacquin, M. F. *et al.*, 1982; Whitehead, M. C. and Frank, M. E., 1983; Marfurt, C. F. and Rajchert, D. M. 1991; Boucher, Y. *et al.*, 2003).

Two classes of second-order nociceptive neurons reside in Vc and NTS. The majority tend to be of the wide-dynamic-range (WDR) type and respond, in graded fashion, to both innocuous and noxious somatosensory stimuli (Dubner, R. and Bennett, G. J., 1983; Sessle, B. J., 1987). The existence of WDR cells is possible due to the convergence of nociceptive and non-nociceptive peripheral afferents onto second-order cells. As the stimulus intensity increases from innocuous to noxious, the second-order cell integrates the afferent volleys first from non-nocicepive cells and then from nociceptors as well. Thus, an innocuous stimulus elicits a low level of activity from WDR cells relative to a noxious stimulus that will evoke larger responses. The other class of second-order nociceptor includes those that respond exclusively to high-intensity, noxious stimuli. These nociceptive-specific (NS) cells receive input exclusively from peripheral C- or Aδ- fibers (Villanueva, L. *et al.*, 1988). Electrophysiolgical studies have revealed that relative to the numbers of WDR-type cells, NS cells tend to be less prevalent, at least in Vc (see, e.g., Carstens, E. *et al.*, 1998). Nociceptors sensitive to chemical irritants exist in both classes of cells (Hu, J. W., 1990; Carstens, E. *et al.*, 1998; Simons, C. T. *et al.*, 1999; Dessirier, J. M. *et al.*, 2000b). Interestingly, both neuron types exhibit similar response characteristics to chemical stimuli. Specifically, they tend to be broadly tuned, with a given Vc neuron capable of responding to a variety of noxious chemicals (Carstens, E. *et al.*, 1998; Simons, C. T. *et al.*, 1999; Dessirier, J. M. *et al.*, 2000b) (Figure 2). This suggests that either peripheral nociceptors express receptor mechanisms to a broad range of irritant chemicals or, alternatively nocieptors in the periphery are specifically tuned, but convergence of these neurons in Vc broadens the tuning characteristic of central neurons. The former explanation is most parsimonious with peripheral fiber and trigeminal ganglion studies in which a single nociceptive fiber or ganglion cell responds to multiple chemical irritants (Wang, Y. *et al.*, 1993; Bryant, B. P. and Moore, P. A., 1995; Liu, L. and Simon, S. A., 1996a; 1996c; Liu, L. *et al.*, 1997; Liu, L. and Simon, S. A., 1997; 1998; Steen, K. H. *et al.*, 1999).

From the first central relay in the trigeminal complex or NTS, oral somatosensory information remains segregated as it is conveyed to third-order sites. In humans, the dorsal column pathway transmits tactile information from layers III–IV of the trigeminal complex to the contralateral ventroposteriomedial (VPM) thalamus (Kandel, E. R. *et al.*, 2000). The anterolateral tract conveys thermal and nociceptive signals from superficial layers to a more lateral thalamic region, the contralateral

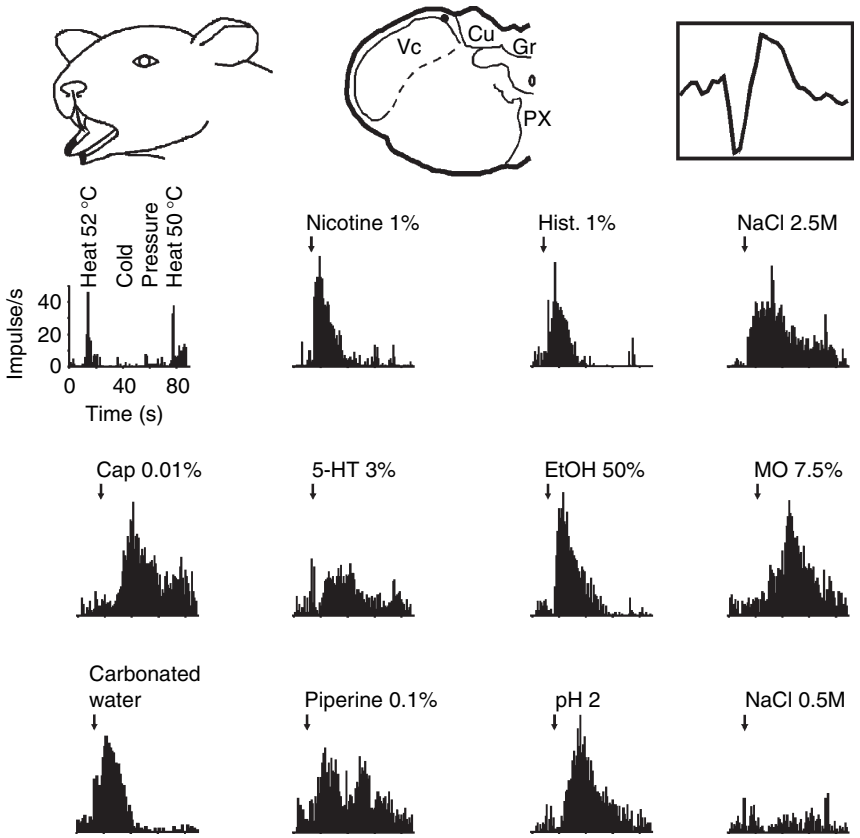

Figure 2 Nonselective responses of Vc neuron to different oral irritants. The figurines in the upper row show, from left to right, a drawing of the rat's face with the receptive field of this neuron on the tongue and chin (black), a cross-section of the medulla showing the recording site (dot) in the superficial part of dorsomedial Vc, and the action potential waveform. The lower three rows show peristimulus–time histograms (PSTHs, bin width 1 s) of responses to various stimuli. Calibrations given in left-hand PSTH, second row. Cap, capsaicin; Cu, cunate n.; EtOH, ethanol; Gr, gracile n.; Hist., histamine; 5-HT, serotonin; MO, mustard oil; pH2, HCl at pH of 2. PX, pyramidal decussation; Vc, trigeminal subnucleus caudalis. Reproduced from Carstens, E., Iodi Carstens, M., Dessirier, J. M., O'Mahony, M., Simons, C. T., Sudo, M., and Sudo, S. 2002. It hurts so good: oral irritation by spices and carbonated drinks and the underlying neural mechanisms. Food Qual. Pref. 13, 431–443, with permission from Elsevier; adapted from Carstens, E., Kuenzler, N., and Handwerker, H. O. 1998. Activation of neurons in rat trigeminal subnucleus caudalis by different irritant chemicals applied to oral or ocular mucosa. J. Neurophysiol. 80, 4654–4692.

ventroposteriolateral (VPL) thalamus (Kandel, E. R. *et al.*, 2000). In rodents, where many of the functional anatomical studies have been completed, ascending somatosensory information has an obligatory relay in the contralateral pontine parabrachial nucleus (Feil, K. and Herbert, H., 1995). From the parabrachial nucleus, somatosensory projections are to the appropriate regions of the ventroposterior thalamus.

Following thalamic processing, ascending anterolateral tract and dorsal column pathways project to the somatosensory (SI) cortex, an area found in the postcentral gyrus of the anterior parietal lobe. Somatosensory projections from the thalamus are organized such that a representation of the body is mapped onto the cortex (Kandel, E. R. *et al.*, 2000). This map, known as a homunculus, is arranged so that body regions having greater sensory acuity occupy a larger region of the SI cortex. Thus, oral structures (lips, teeth, tongue, and pharynx) occupy a relatively large region of lateral SI cortex compared to legs and trunk, which occupy a smaller region of medial SI cortex. Projections from SI are directed toward secondary cortical areas in the parietal lobe (LaMotte, R. H. and Mountcastle, V. B., 1979) and tertiary areas in the insula and orbitofrontal cortex (Verhagen, J. V. *et al.*, 2003; Kadohisa, M. *et al.*, 2004; 2005). Oral somatosensory inputs into the insula and orbitofrontal cortex are of particular interest to taste and flavor interactions. The primary gustatory cortex is found in the insula (Yaxley, S. *et al.*, 1990; Small, D. M.

et al., 1999; Stapleton, J. R. *et al.*, 2006), and the orbitofrontal cortex receives converging taste, smell, somatosensory, and visual information to encode stimulus valence (Rolls, E. T. and Baylis, L. L., 1994; Critchley, H. D. and Rolls, E. T., 1996).

4.18.2 Oral Chemesthesis: Physiology

The role of chemonociceptive neurons in the oral cavity is to signal the presence of stimuli that are potentially or overtly damaging prior to ingestion. However, not all stimuli that activate nociceptors are damaging. For example, capsaicin, the pungent principle in chili peppers, binds to the vanilloid-1 receptor (TRPV1 or VR-1) expressed in nociceptors (Caterina, M. J. *et al.*, 1997; Tominaga, M. *et al.*, 1998; Caterina, M. J. *et al.*, 1999; Nagy, I. and Rang, H. P., 1999; Caterina, M. J. *et al.*, 2000) to elicit a burning sensation that, in some cuisines, is highly sought after. Capsaicin, however, is relatively benign and TRPV1 is ordinarily present in nociceptors to detect the presence of noxious thermal or acidic stimuli (Tominaga, M. *et al.*, 1998; Cesare, P. *et al.*, 1999; Nagy, I. and Rang, H. P., 1999; Jordt, S. E. *et al.*, 2000).

The process of detecting chemesthetic stimuli is initiated at the receptor level. In the oral cavity, trigeminal ganglion neurons express a variety of receptors that are activated by the presence of chemical irritants (Wang, Y. *et al.*, 1993; Bryant, B. P. and Moore, P. A., 1995; Liu, L. and Simon, S. A., 1996a; 1996c; 1997; Liu, L. *et al.*, 1997; Liu, L. and Simon, S. A., 1998; Steen, K. H. *et al.*, 1999). A variety of methods, including patch-clamp techniques and calcium imaging, have been used to study the response characteristics of trigeminal ganglion neurons to oral irritants, and in the last decade, a wealth of information has been generated regarding the receptor and cellular mechanisms underlying irritant chemical detection. The great majority of known chemoirritant receptors are of the transient receptor potential (TRP) superfamily (for review see Clapham, D. E., 2003; Wang, H. and Woolf, C. J., 2005) of cation channels. All mammalian TRP channels are 6-transmembrane polypeptides that assemble as tetramers to form cation channels (Clapham, D. E., 2003). To date, TRP channels have been shown to transduce and discriminate a large variety of sensations ranging from taste (sweet, bitter, and umami) (Perez, C. A. *et al.*, 2002; Zhang, Y. *et al.*, 2003) to temperature (Caterina, M. J. *et al.*, 1997; 1999; McKemy, D. D. *et al.*, 2002; Peier, A. M. *et al.*, 2002b; Smith, G. D. *et al.*, 2002; Xu, H. *et al.*, 2002), pressure (Mizuno, A. *et al.*, 2003; Suzuki, M. *et al.*, 2003), and noxious chemicals (Caterina, M. J. *et al.*, 1997; Tominaga, M. *et al.*, 1998; Trevisani, M. *et al.*, 2002; Yang, B. H. *et al.*, 2003; Bandell, M. *et al.*, 2004; Jordt, S. E. *et al.*, 2004; Bautista, D. M. *et al.*, 2005; Macpherson, L. J. *et al.*, 2005; Moqrich, A. *et al.*, 2005). Interestingly, most of the chemosensitive TRP channels identified thus far are also responsive to other noxious stimuli. For instance, the first channel to be identified as chemosensitive, TRPV1, has been shown to be activated by noxious heat (>43 °C) in addition to the irritants capsaicin, acids (Caterina, M. J. *et al.*, 1997; Tominaga, M. *et al.*, 1998), ethanol (Trevisani, M. *et al.*, 2002), eugenol (Yang, B. H. *et al.*, 2003), and camphor (Xu, H. *et al.*, 2005) (see Table 1).

The chemosensitive TRP channels come from three different subfamilies. The TRPV family is characterized primarily by its thermosensitvity (Clapham, D. E., 2003). Of the six members in this subfamily, four appear to be thermosensitive and three express chemosensitivity (Table 1). In addition to TRPV1's well-known sensitivity to noxious heat, capsaicin (Caterina, M. J. *et al.*, 1997), acidic stimuli (Tominaga, M. *et al.*, 1998), and ethanol (Trevisani, M. *et al.*, 2002), TRPV3, responds to innocuous warmth (>30 °C) (Peier, A. M.

Table 1 Thermo- and chemosensitive transient receptor potentials (TRPs)

	Temperature sensitivity	*Chemical sensitivity*
TRPV1 (VR1)	>43 °C	Capsaicin, acid, ethanol, eugenol camphor
TRPV2 (VRL-1)	>52 °C	
TRPV3	>30 °C	Camphor, carvacol, eugenol, thymol
TRPV4	>24 °C	Acid
TRPM8	<25 °C	Menthol, icilin
TRPA1	<18 °C	Allyl isothiocyanate (mustard oil), cinnamic aldehyde, methyl salicylate (wintergreen oil), eugenol (clove oil), gingerol (ginger), allicin (garlic)

et al., 2002b; Smith, G. D. *et al.*, 2002; Xu *et al.*, 2002) as well as camphor (Moqrich, A. *et al.*, 2005), carvacol, eugenol, and thymol (Xu, H. *et al.*, 2006). TRPV4 is responsive to pressure (Mizuno, A. *et al.*, 2003; Suzuki, M. *et al.*, 2003), innocuous warming (>24 °C) (Guler, A. D. *et al.*, 2002), and low pH (Suzuki, M. *et al.*, 2003).

Like the TRPV subfamily, the TRPM and TRPA receptor subfamilies display sensitivity to multiple stimuli (Table 1). In regard to chemesthesis, TRPM8 and TRPA1 (ANKTM1) are well characterized. TRPM8 has been shown to respond to cold (<25 °C) as well as the cooling agents menthol and icillin (McKemy, D. D. *et al.*, 2002; Peier, A. M. *et al.*, 2002a; Andersson, D. A. *et al.*, 2004; Chuang, H. H. *et al.*, 2004). At high concentrations, menthol has been shown to evoke activity in nociceptive neurons (Xing, H. *et al.*, 2006) and elicit sensations of both cooling and irritation when applied to humans (Green, B. G. 1992; Cliff, M. A. and Green, B. G., 1994; Dessirier, J. M. *et al.*, 2001a). Initial studies indicated that TRPA1 was responsive to noxious cold (<18 °C) (Story, G. M. *et al.*, 2003), although this has been challenged (Jordt, S. E. *et al.*, 2004) and it was recently reported that knockout mice lacking TRPA1 do not exhibit any deficit in responsiveness to noxious cold (Bautista, D. M. *et al.*, 2006). Subsequently, TRPA1 has been shown to additionally respond to pungent compounds including mustard oil, cinnamic aldehyde, wintergreen oil, clove oil, ginger, and garlic (Bandell, M. *et al.*, 2004; Jordt, S. E. *et al.*, 2004; Bautista, D. M. *et al.*, 2005; Macpherson, L. J. *et al.*, 2005) (see Table 1).

Additional receptor families have been implicated for the detection of other oral irritants. For instance, in addition to TRPV1, acid-sensitive ion channels (ASICs) have been shown to be present in trigeminal ganglion cells (Olson, T. H. *et al.*, 1998) and respond to low pH (Lingueglia, E. *et al.*, 1997; Waldmann, R. *et al.*, 1997; Price, M. P. *et al.*, 2001). Similarly, nicotinic acetylcholinergic receptors signal the presence of nicotine irritation (Liu, L. and Simon, S. A. 1996d; Dessirier, J. M. *et al.*, 1998; Liu, L. *et al.*, 1998; Marubio, L. M. *et al.*, 1999).

Electrophysiological recordings elicited by lingual application of chemesthetic stimuli have been made along the entire neural pathway. Remarkably, there is great correspondence between the patterns of activity generated at different levels of the neuraxis. Unlike other systems, activity generated in the periphery seems to be faithfully transmitted to higher brain levels, thus providing a solid foundation for studying the neural correlates of irritant sensation.

Lingual nerve recordings have been made in response to application of a variety of chemesthetic stimuli including acids (Sostman, A. L. and Simon, S. A., 1991; Komai, M. and Bryant, B. P., 1993), vanilloids (Wang, Y. *et al.*, 1993), menthol (Wang, Y. *et al.*, 1993; Lundy, R. F., Jr. and Contreras, R. J., 1994; 1995), ethanol (Danilova, V. and Hellekant, G. 2002), and astringent (Shiffman, S. S., *et al.*, 1992) and tingling (Bryant, B. P. and Mezine, I., 1999) compounds. The difficulty in isolating single C- and Aδ-fibers makes this technique extremely labor intensive and, consequently, whole-nerve recordings are often made. Despite these technical limitations, when combined with patch-clamp and calcium-imaging studies of trigeminal ganglion cells, important information has been gathered detailing cellular processes and coding mechanisms. Indeed, increasing numbers of studies suggest that the processing of chemoirritant information remains segregated from the processing of non-nociceptive chemically evoked sensations. For instance, chemical irritants (e.g., capsaicin, pentanoic acid, and mustard oil) tend to activate the same population of chemosensitive trigeminal cells, whereas menthol, when delivered at a low, nonirritating dose, activates a different population (Jordt, S. E. *et al.*, 2004; Abe, J. *et al.*, 2005; Kobayashi, K. *et al.*, 2005). Some of the overlap in chemical sensitivity is the result of a specific receptor being activated by multiple irritants as is the case with TRPV1 which is activated by vanilloids (Caterina, M. J. *et al.*, 1997), protons (Tominaga, M. *et al.*, 1998; Jordt, S. E. *et al.*, 2000), and ethanol (Trevisani, M. *et al.*, 2002). Additionally, multiple studies have shown individual trigeminal ganglion cells or fibers to respond to a diverse sample set of chemical irritants, suggesting that multiple receptor mechanisms are coexpressed in the same cell. The fact that TRPM8 is expressed in a population of neurons separate from those expressing TRPV1 or TRPA1 (Jordt, S. E. *et al.*, 2004; Abe, J. *et al.*, 2005; Kobayashi, K. *et al.*, 2005) provides a mechanism by which chemically evoked irritant and thermal sensations are kept separate. If the pungency associated with high menthol concentrations can be attributed to activation of TRPA1, then a chemesthetic model supporting the separate processing of irritant and thermal stimuli can be developed. However, to date, rodent TRPA1 has not been shown to be menthol sensitive.

Centrally, *c-fos* immunohistochemistry has been used to show that similar populations of neurons in superficial Vc are activated by lingual application of a variety of chemical irritants including nicotine,

capsaicin, piperine, histamine, acids, and high salt concentrations (Carstens, E. *et al.*, 1995; Simons, C. T. *et al.*, 1999; Dessirier, J. M. *et al.*, 2000; Carstens, E. *et al.*, 2001; Sudo, S. *et al.*, 2003). However, immunohistochemical studies are static representations of neural activity and cannot show whether a given neuron responds to multiple chemical stimuli. Thus, electrophysiological recordings of Vc neural activity are necessary to delineate the response properties of chemosensitive neurons. To date, extracellular recordings suggest that Vc neurons respond to multiple classes of chemoirritants (Carstens, E. *et al.*, 1998; Simons, C. T. *et al.*, 1999; Dessirier, J. M. *et al.*, 2000; Sudo, S. *et al.*, 2002; Simons, C. T. *et al.*, 2003c; Sudo, S. *et al.*, 2003; Simons, C. T. *et al.*, 2004) (Figure 2). Recent studies indicate that neurons in superficial laminae of Vc that respond to noxious tongue cooling also respond to menthol, and that the large majority of these additionally respond to noxious heat, capsaicin, mustard oil, and other irritant chemicals (Carstens, E. *et al.*, 2005) (Figure 3). This multiple sensitivity is true for WDR and NS cell types. Thus, although in the periphery, chemoirritation may be coded along labeled lines, at the level of the first central synapse, this specificity appears to be lost.

Few studies have looked at the chemosensitivity of neurons residing in thalamus or somatosensory cortex. Injections of capsaicin under the skin of the lip in rat increased spontaneous firing rate of thalamocortical neurons within 15 min and resulted in reorganization of VPM and SI whisker receptive fields within 1 h (Katz, D. B. *et al.*, 1999). These findings are in contrast to studies at the brainstem and spinal level wherein capsaicin induces immediate increases in neuronal firing (e.g., Carstens, E. *et al.*, 1998; Dessirier, J. M. *et al.*, 2000), and the time course for capsaicin-induced reorganization is significantly shorter (Simone, D. A. *et al.*, 1991; Pettit, M. J. and Schwark, H. D., 1996; Chiang, C. Y. *et al.*, 1997). Capsaicin has been shown to activate neurons in higher cortical levels including the orbitofrontal cortex and amygdala (Rolls, E. T. *et al.*, 2003; Kadohisa, M. *et al.*, 2004; 2005). Of the population of macaque orbitofrontal neurons responding to taste, temperature, or viscosity, nearly 16% also responded to capsaicin (Kadohisa, M. *et al.*, 2004). Notably, the response characteristics of neurons in orbitofrontal cortex activated by thermal stimuli were different from those activated by capsaicin, indicating that the representation of capsaicin in this region is different from other somatosensory stimuli such as temperature.

Perceptually, chemesthetic sensations elicited by various irritant chemicals are often verbalized using the same descriptor. Typically, these sensations are described as burning or pungent regardless of whether the stimulus is, for example, capsaicin or menthol. However, it is unknown whether these chemically diverse compounds all elicit sensations that are qualitatively identical or, alternatively, whether the compounds evoke qualitatively different sensations that are described as similar due to a limited vocabulary. Neurophysiological evidence has shown that a single nociceptor can express multiple receptor subtypes and respond to a variety of chemoirritants. However, subjects can easily discriminate the irritant

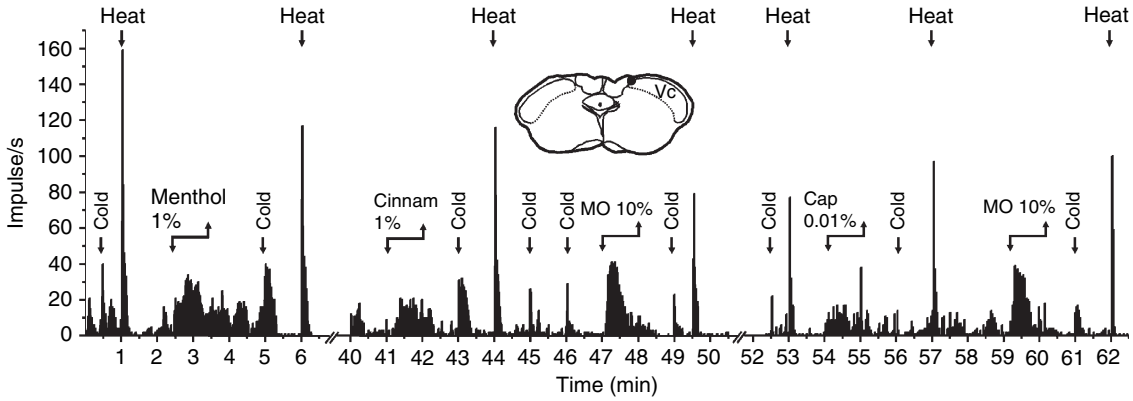

Figure 3 Representative individual example of cold- and menthol-responsive Vc unit that additionally responded to noxious heat and other irritant chemicals. Shown are peristimulus–time histograms (PSTHs; bin width 1 s) of activity. Arrows indicate time of application of noxious cold (0–3 °C water) or heat (53 °C water) stimuli, and bars with downward and upward arrows indicate start and end of chemical application. Cinnam: cinnamaldehyde; MO, mustard oil; Cap, capsaicin. Inset shows recording site (dot).

sensation evoked from different chemical compounds. Certainly, temporal cues assist subjects in this discrimination task. For instance, some compounds, such as allyisothiocyanate, have a quick onset and relatively short duration, whereas others have a slower onset (nicotine) or longer duration (capsaicin). Further studies are needed to delineate whether chemesthetic submodalities exist. Further advances in neuroimaging techniques might allow investigators to determine the neural underpinnings that allow subjects to differentiate chemical irritants.

4.18.3 Chemoirritation: Temporal Phenomena

Most sensory systems maintain sensitivity to conditions of repeated or prolonged stimulation by a process called adaptation. Adaptation is a specialized cellular response that results in a decreased number of evoked action potentials despite a maintained stimulus. Cellular adaptation results in the loss of the conscious perception of a constant stimulus. Unique to the chemesthetic sense, irritant stimuli often evoke patterns of sensation that do not conform to the classic models of adaptation. Indeed the sensation elicited by irritant stimuli can increase or decrease with repeated stimulation depending upon chemical compound and the interstimulus interval (ISI).

Sensitization is the phenomenon encountered when a chemesthetic stimulus elicits an irritant sensation of progressively increasing magnitude when applied repeatedly to the tongue (Stevens, D. A. and Lawless, H. T., 1987; Green, B. G., 1989; Cliff, M. A. and Green, B. G., 1996; Prescott, J. and Stevenson, R. J., 1996b; Dessirier, J. M. *et al.*, 1997; Dessirier, J. M. *et al.*, 1999; Prescott, J. and Swain-Campbell, N., 2000). The most well-studied sensitizing irritant is the vanilloid capsaicin. Numerous investigators have noted that when capsaicin is applied to the oral mucosa at ISIs of less than 3 min, the perceived irritant sensation grows (Figure 4(a), left). However, following a short hiatus of greater than 3 min, a condition of self-desensitization (Figure 4, right) develops where further capsaicin applications are perceived as less irritating (Green, B. G., 1989; Geppetti, P. *et al.*, 1993; Cliff, M. A. and Green, B. G., 1996; Green, B. G., 1998; Green, B. G. and Rentmeister-Bryant, H., 1998). With continued application, the perceived irritation builds up again to eventually reach the same level obtained prior to

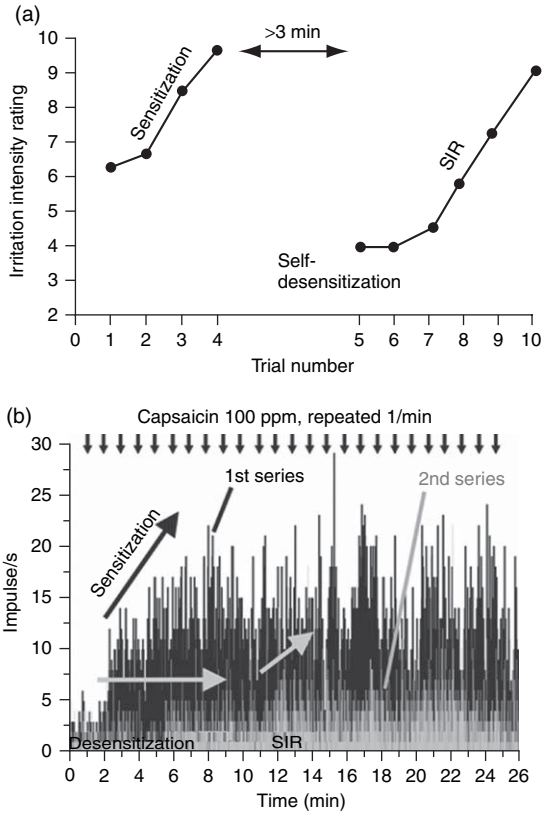

Figure 4 Capsaicin sensitization, desensitization, and stimulus-induced recovery. (a) Graph plots human psychophysical intensity ratings of irritation elicited by repeated application of capsaicin (10 ppm) to the tongue at 1-min interstimulus intervals. (b) Example of response of Vc neuron to repeated application of capsaicin (at arrows). Black histogram shows the response to initial series of capsaicin applications and gray histogram shows the response to second series of applications 30 min after the end of the first series. Note the progressive increase in response to the first series of applications (sensitization), the absence of response to the initial capsaicin applications in the second series (desensitization) with a delayed increased (stimulus-induced recovery = SIR). (a) Data adapted from Green, B. G. 1996. Rapid recovery from capsaicin desensitization during recurrent stimulation. Pain 68, 245–253. (b) Adapted from Dessirier, J. M., Simons, C. T., Sudo, M., Sudo, S., and Carstens, E. 2000b. Sensitization, desensitization and stimulus-induced recovery of trigeminal neuronal responses to oral capsaicin and nicotine. J. Neurophysiol. 84, 1851–1862.

desensitization (Figure 4(a), right); this condition has been termed stimulus-induced recovery (SIR) (Green, B. G., 1996; Green, B. G. and Rentmeister-Bryant, H., 1998). Other vanilloids, including piperine (Stevens, D. A. and Lawless, H. T., 1987; Green, B. G., 1996; Dessirier, J. M. *et al.*, 1999), acids (Green, B. G., 1996; Dessirier, J. M. *et al.*, 2000a), and high concentrations of salt (Dessirier, J. M. *et al.*, 2001b),

elicit patterns of irritation similar to those evoked by capsaicin. Allylisothiocyanate (Simons, C. T. *et al.*, 2003b), nicotine (Dessirier, J. M. *et al.*, 1999), menthol (Cliff, M. A. and Green, B. G., 1994; 1996; Green, B. G. and McAuliffe, B. L., 2000; Dessirier, J. M. *et al.*, 2001a), zingerone (Prescott, J. and Stevenson, R. J., 1996a), cinnamaldehyde (Prescott, J. and Swain-Campbell, N., 2000), and ethanol (Prescott, J. and Swain-Campbell, N., 2000), however, show a pronounced desensitization with repeated application. Figure 5(a) shows desensitization with menthol. Furthermore, reapplication of the same chemical

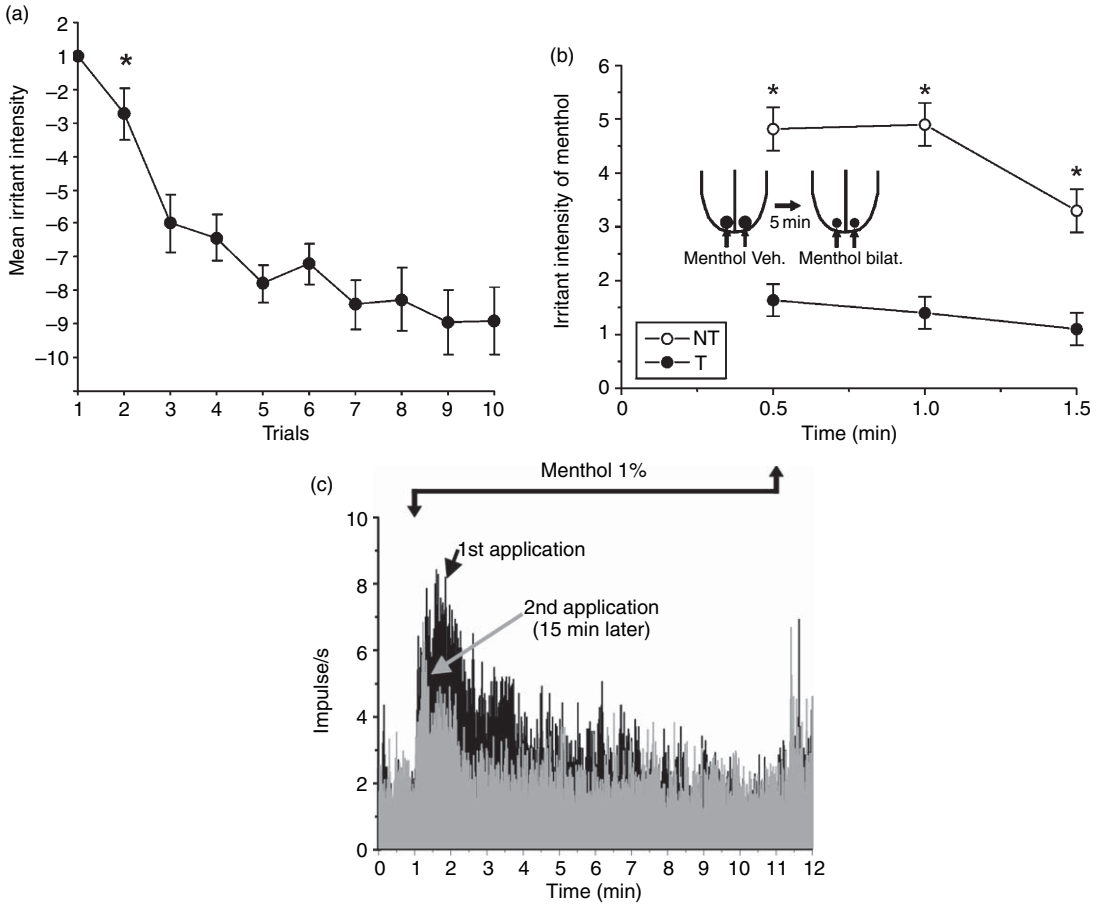

Figure 5 Menthol desensitization. (a) Mean irritant intensity reported 25 s following stimulus onset as a function of trials of menthol (19.2 mM) delivered sequentially at 1 min intervals. Intensity ratings were made using a bipolar category scale in which the magnitude of irritation elicited by the initial stimulus is rated 1; increasingly negative numbers indicate weaker intensity compared to the first trial. Error bars: SE *: significantly different from initial rating ($P < 0.05$, ANOVA). (b) Menthol self-desensitization, assessed using half-tongue two-alternative forced-choice procedure. Menthol was applied to one side of the tongue and vehicle to the other (left-hand inset showing figurine of tongue), followed 5 min later by bilateral application of menthol (right-hand inset). Graph plots the mean irritant intensity for the menthol-treated (T, filled circles) and nontreated (NT, open circles) side of the tongue vs. time following bilateral application of menthol. Note the significant self-desensitization. Error bars: SE Asterisks indicate significant difference between T and NT ($P < 0.05$, *t*-test). (c) Desensitization of responses of Vc neurons to menthol. Black peristimulus–time histogram (PSTH, bin width 1 s) shows averaged responses of 14 Vc neurons to the first application of menthol to the dorsal tongue for 10 min by constant flow (downward and upward arrows denote onset and cessation of menthol application). Note the initial increase in response followed by a decline to baseline levels (desensitization) despite continued menthol, similar to the psychophysical ratings (a). Gray PSTH shows averaged response of the same group of Vc neurons to a second application of menthol 15 min later. Note that the response was smaller compared to the first menthol application (self-desensitization), also similar to the psychophysical findings (b). (a) From Dessirier, J. M., O'Mahony, M., and Carstens, E. 2001a. Oral irritant properties of menthol: sensitizing and desensitizing effects of repeated application and cross-desensitization to nicotine. Physiol. Behav. 73, 25–36. (b) From Dessirier, J. M., O'Mahony, M., and Carstens, E. 2001a. Oral irritant properties of menthol: sensitizing and desensitizing effects of repeated application and cross-desensitization to nicotine. Physiol. Behav. 73, 25–36.

following a hiatus elicits weaker irritation. An example of this self-desensitization with menthol is shown in Figure 5(b).

In addition to sensitization, desensitization, and SIR, many compounds cross-interact to influence another irritant's temporal properties. Information from these studies sheds important light on the transduction and coding mechanisms underlying chemesthesis. For instance, following a hiatus from capsaicin application, the irritant sensation evoked by either piperine (Green, B. G., 1996), nicotine (Dessirier, J. M. *et al.*, 1997), mustard oil (Simons, C. T. *et al.*, 2003b), citric acid (Dessirier, J. M. *et al.*, 2000a), or carbonated water (Dessirier, J. M. *et al.*, 2001c) is reduced. Similar results have been obtained with menthol and nicotine (Dessirier, J. M. *et al.*, 2001a). This phenomenon has been termed cross-desensitization. Cross-sensitization and cross-SIR have been noted for NaCl–capsaicin (Dessirier, J. M. *et al.*, 2001b) and citric acid–capsaicin (Dessirier, J. M. *et al.*, 2000a), respectively. When the temporal chemesthetic properties of an irritant are influenced by the application of a different irritant, several conclusions can be drawn. For instance, the results can be used to suggest that the two irritants share a common receptor mechanism as has been shown with capsaicin and piperine or ethanol. Similarly, for irritant compounds that activate different receptors, like capsaicin and mustard oil or nicotine and menthol, cross-interactions suggest that the same nociceptive cells or neural pathways are involved in the processing of the chemesthetic information.

The different patterns of sensation (i.e., sensitization, desensitization, and SIR) most likely reflect competing cellular mechanisms that differentially dominate during the continued application of the chemical irritant. To date, there is no evidence that sensitization occurs within a single isolated trigeminal ganglion cell. In fact, with repeated application of capsaicin, tachyphylaxis has been observed whereby the size of the evoked inward current decreases (Cholewinski, A. *et al.*, 1993; Liu, L. and Simon, S. A. 1996b; Koplas, P. A. *et al.*, 1997). Thus, the mechanism proposed to mediate sensitization is one of spatial summation (Carstens, E. *et al.*, 2002). In this model (Figure 6), a chemoirritant applied to the tongue is believed to diffuse into the lingual tissue where it accesses previously quiescent nociceptive cells. As long as the pool of irritant stimuli is maintained, sensitization is believed to continue until the rate of diffusion is equaled by the rate at which the stimulus is broken down or absorbed into the blood stream. When the diffusion rate equals the absorption rate, the perceived irritant is hypothesized to plateau and when the absorption rate is greater than the diffusion rate, mechanisms subserving tachyphylaxis dominate, and a state of desensitization results.

Electrophysiological studies in rat Vc neurons have indicated that a remarkable correlation exists between their chemical responsivity and the sensations perceived in human psychophysical studies. Capsaicin, when applied with a short ISI to the rat tongue, elicits activity in Vc neurons that progressively increases over time to reach a plateau approximately 7 min following stimulus administration (Figure 4(b)) (Dessirier, J. M. *et al.*, 2000b). When capsaicin is reapplied following a

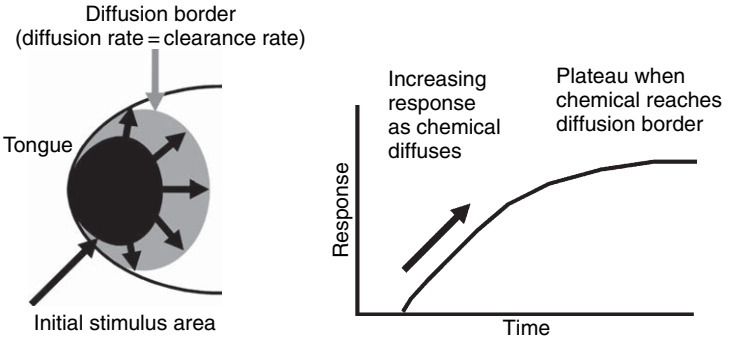

Figure 6 Spatial recruitment of lingual nociceptors to explain sensitization. Left-hand drawing shows initial area (black) of chemical stimulus applied to the tongue. With repeated application, the area increases to a maximum diffusion border (gray) where the rate of chemical diffusion equals the rate of clearance. As the chemical diffuses, it progressively excites more nociceptors by spatial recruitment, causing a progressive rise in sensation (right-hand graph) that plateaus as the chemical reaches its diffusion border.

hiatus of 15 min, evoked activity is significantly delayed; however, further administration causes the firing rate to eventually increase (Figure 4(b)). These data are suggestive of desensitization and SIR, respectively. Conversely, menthol and other chemicals elicit a desensitizing pattern of irritation in human psychophysical studies (see above) which is also reflected in the response pattern of Vc neurons. When applied to the tongue of anesthetized rats, menthol (Carstens, E. *et al.*, 2005), nicotine (Dessirier, J. M. *et al.*, 2000b), and allylisothiocyanate (Simons, C. T. *et al.*, 2004) have been shown to evoke activity in Vc neurons that decreases with continued application. An example with menthol is shown in Figure 5(c) (black histogram). Note that when menthol was reapplied after a 15 min hiatus, it elicited a weaker response (Figure 5(c), gray histogram) consistent with human psychophysical studies (Figure 5(b)).

4.18.4 Irritant–Taste Interactions

Foods containing irritant chemicals continue to gain in popularity in the United States and elsewhere. However, despite the increasing consumption of spicy foods, few studies have looked at irritation–taste interactions. From a nutritional perspective, taste is a major contributor to diet selection (Scott, T. R. and Verhagen, J. V., 2000). Thus, alterations in perceptions of taste resulting from the presence of irritant stimuli could impact nutritional status. Moreover, the existence of irritant–taste interactions could alter the way sensory methodologies are utilized within the food industry. Many irritant chemicals evoke sensitizing or desensitizing patterns of irritation (see above). If these chemicals similarly modulate sensations of taste, new precautions or methodologies must be developed to ensure that the sensory data obtained from spicy products are useful.

Once thought to be tasteless, vanilloids (capsaicin, piperine, and zingerone), as well as menthol, have recently been shown to evoke a bitter taste from a subpopulation of individuals when applied directly to taste papillae (Green, B. G. and Schullery, M. T., 2003; Green, B. G. and Hayes, J. E., 2003; 2004). For those subjects sensitive to the taste quality of capsaicin and zingerone, the intensity appears to be stronger when applied to circumavallate as opposed to fungiform papillae. The mechanism appears to be vanilloid activation of taste receptor cells. However, whether these compounds activate TRPV1 or a particular receptor from the T2R bitter family is still unclear.

Despite the recent observations that most, if not all, irritants evoke a sensation of taste, anecdotal evidence suggests that these same pungent chemicals modify the gustatory qualities of many foods (Prescott, J. *et al.*, 1993). Subjects often report not liking pungent spices (e.g., chili peppers) because the irritant quality blocks or masks the normal taste quality of the food they want to enjoy. A number of psychophysical studies have attempted to quantify the effects reported anecdotally. Most investigations examined the impact of vanilloids (capsaicin and piperine) on taste perception (Szolcsányi, J., 1977; Lawless, H. T. and Stevens, D. A., 1984; Lawless, H. T. *et al.*, 1985; Cowart, B. J., 1987; Prescott, J. *et al.*, 1993; Karrer, T. and Bartoshuk, L., 1995; Prescott, J. and Stevenson, R. J., 1995; Stevenson, R. J. and Prescott, J., 1997, Simons, C. T. *et al.*, 2002); however, CO_2 has also been addressed (Cometto-Muñiz, J. E. *et al.*, 1987; Cowart, B. J., 1998).

Initial studies reported that recognition thresholds of taste stimuli were not affected by rinsing with aqueous solutions of capsaicin (Szolcsányi, J., 1977). However, recognition thresholds are notoriously inconsistent and often show great intraindividual variability (O'Mahony, M. *et al.*, 1976). At suprathreshold concentrations of taste stimuli, the effects of capsaicin appear to be variable. Following this initial study, Lawless H. T. and Stevens D. A. (1984) noted modest-to-significant reductions in the perceived intensity of sour, bitter, and sweet stimuli following a whole-mouth capsaicin rinse. The effect of piperine was more pronounced with a significant suppression noted of all taste qualities. Similarly, evaluated as sucrose– or NaCl–capsaicin mixtures, perceived sweet intensity was decreased, whereas there was minimal impact on perceived saltiness (Prescott, J. *et al.*, 1993). These findings were confirmed in a subsequent study (Stevenson, R. J. and Prescott, J., 1997). Most recently, capsaicin pretreatment was found to suppress the perceived intensity of sucrose-induced sweetness, quinine-induced bitterness, and glutamate-induced umami (Simons, C. T. *et al.*, 2002). It is tempting to speculate that across these studies, the taste sensations that consistently show suppression when capsaicin irritation is present are those that typically involve G-protein-coupled receptors (GPCRs); however, it should be emphasized that quinine is thought to have a mode of action that is independent of GPCRs (Chen, Y. and Herness, M. S., 1997).

Some of this interstudy variability can be attributed to the method of capsaicin/tastant delivery as evidence suggests that pretreating the oral cavity with irritants prior to evaluating tastes results in a greater apparent reduction in taste intensity compared to rinsing with irritant–tastant mixtures (Cowart, B. J., 1987). Moreover, confounding influences of solution concentrations and temperature have not always been controlled. However, despite these methodological differences, pretreating the oral cavity with capsaicin or piperine appears to consistently suppress the intensity of perceived sweetness.

Several studies also investigated the effect of capsaicin desensitization on taste perception (Gilmore, M. M. and Green, B. G., 1993; Karrer, T. and Bartoshuk, L., 1995; Simons, C. T. *et al.*, 2002). Capsaicin desensitization reduced the sensation elicited by citric acid and NaCl, but this effect was minimized when controlling for context effects (Gilmore, M. M. and Green, B. G., 1993). In fact, when controlling for context effect, only the sensations elicited by the highest levels of NaCl or citric acid were reduced. At high concentrations, both citric acid and NaCl evoke irritant sensations that are difficult to separate from the taste sensations. The reduction in sensation reported at the high tastant concentrations, therefore, might be due to capsaicin's ability to cross-desensitize the irritation elicited by NaCl or citric acid as opposed to desensitizing taste sensation *per se*. Similar results were found using a different methodology (Simons, C. T. *et al.*, 2002). Self-desensitization evoked by low capsaicin concentrations (1.5 or ppm) had no effect on the taste sensations elicited by sucrose, quinine, monosodium glutamate, NaCl, or citric acid. However, at high capsaicin concentrations (100 ppm or more), self-desensitization led to a reduction in the perceived bitter intensity elicited by propthiouracil or quinine as well as the saltiness and sourness of NaCl and citric acid solutions (Karrer, T. and Bartoshuk, L., 1995). However, at lower capsaicin concentrations (10 ppm), these same authors saw no effect of capsaicin desensitization on perceived intensity of taste solutions (Karrer, T. and Bartoshuk, L., 1995).

The presence of CO_2 appears to variably modulate the perceived intensity of taste solutions. When added to aqueous solutions of sucrose, citric acid, NaCl, or quinine, CO_2 was found to slightly increase the perceived intensity of salty and sour sensations (Cometto-Muñiz, J. E. *et al.*, 1987). However, these results were not interpreted as a CO_2 enhancement of saltiness or sourness, but instead attributed to subject confusion between the sensation elicited by low concentrations of NaCl or citric acid with the pungent sensation elicited by CO_2. In a subsequent experiment (Cowart, B. J., 1998), carbonation was found to have no effect on total taste intensity of model taste solutions, but increased the intensity of the sweet and salty subcomponents of the stimulus. On the surface, it is surprising that CO_2 would increase the perceived intensity of some tastants, whereas vanilloids tend to have a suppressive effect. However, CO_2, being an acid, is sour and would therefore be expected to increase the perceived intensity of some taste sensations.

Despite the psychophysical evidence for irritant–taste interactions, it is not clearly understood where they occur. Clearly, in the case of vanilloid-evoked taste sensations (Green, B. G. and Schullery, M. T., 2003; Green, B. G. and Hayes, J. E., 2003; 2004), the compound is acting to excite taste receptor cells. However, in the case of irritant modulation of taste sensations, there are a number of potential sites and mechanisms. For instance, it is possible that irritants and tastants interact at the cognitive level as has been proposed for gustation and olfaction. Given the distinct anatomical separation of the olfactory and gustatory neural pathways, this scenario makes sense. However, in the case of oral irritants and tastants, the two chemical modalities stimulate neurons located within the same oral tissue, most notably the tongue. This provides a substrate by which chemicals (i.e., substance P, calcitonin gene-related peptide (CGRP)) released locally from trigeminal nerve endings in response to a noxious stimulus might modulate the activity of taste receptor cells or gustatory neurons (Wang, Y. *et al.*, 1995; Osada, K. *et al.*, 1997; Simon, S. A. *et al.*, 2003). Therefore, it is possible that intermodality communication occurs peripherally. Other potential sites of interaction also exist. Trigeminal primary afferent neurons project not only to brainstem nuclei involved in processing nociceptive information but also send collateral branches to the gustatory NTS (Beckstead, R. M. and Norgren, R., 1979). Similarly, second-order projections from Vc have also been identified in the NTS (Menétrey, D. and Basbaum, A. I., 1987). Therefore, oral irritant and taste information might converge onto second-order neurons residing in the taste nucleus. Nociceptive input could, therefore, directly modulate NTS gustatory neurons or, alternatively, excite inhibitory gamma-amino-*n*-butyric acid (GABA)-ergic or opioidergic interneurons that have been identified within this area (Lynch, W. C.

et al., 1985; Davis, B. J., 1993; Davis, B. J. and Kream, R. M., 1993). Either mechanism of central interaction could suppress the activity of gustatory cells resulting in alterations to taste perception.

4.18.4.1 Peripheral Interactions

Several investigations have addressed the possibility that trigeminal and gustatory interactions occur in the periphery. In particular, three studies have looked directly at the consequence of lingual nerve stimulation on the response of chorda tympani fibers (Wang, Y. *et al.*, 1995; Osada, K. *et al.*, 1997; Simon, S. A. *et al.*, 2003). In the first (Wang, Y. *et al.*, 1995), chorda tympani responses to NaCl were recorded before, during, and after electrical stimulation of the lingual nerve. It was found that the NaCl-induced activity in these fibers was significantly depressed during simultaneous lingual nerve stimulation (Figure 7). The effect was presumed to be due to the release of neuroactive peptides from the peripheral terminals of trigeminal nociceptive nerve endings that directly affected the responses of gustatory neurons to NaCl. Anatomical studies have shown that taste receptor cells or perigemmal neurons express receptors for a variety of neuropeptides including substance P (Chang, G. Q. *et al.*, 1996) and CGRP (van Rossum, D. *et al.*, 1997), both of which are released from C-fiber terminals following electrical stimulation or via an axon reflex (Holzer, P., 1998).

In the second study (Osada, K. *et al.*, 1997), chorda tympani responses to NaCl or KCl were recorded in the presence or absence of capsaicin. The majority of responses to NaCl and KCl were depressed when capsaicin was presented simultaneously with the gustatory stimulus (Figure 8). Interestingly, in a subpopulation of neurons, capsaicin treatment significantly enhanced the NaCl or KCl response. As in the previous study, the attenuated gustatory response was attributed to the presence of neuroactive peptides released in response to capsaicin.

However, with the completion of more recent studies, alternative explanations are possible. For instance, studies suggest that the amiloride-insensitive pathway mediating NaCl sensitivity involves a TRPV1 variant (Lyall, V. *et al.*, 2004; 2005) that responds to the TRPV1 agonists resiniferatoxin and capsaicin. As such, the possibility exists that simultaneous capsaicin application may directly gate the TRPV1 variant to evoke a heightened NaCl or KCl response. Similarly, if the TRPV1 variant has altered desensitization kinetics, capsaicin application might be speculated to result in attenuated NaCl responses. In addition to the potential modulation of the TRPV1 variant, recent studies confirm that capsaicin inhibits voltage-sensitive ion channels expressed in taste receptor cells (Park, K. *et al.*, 2003, Costa, R. M. *et al.*, 2005). The conductance of outwardly rectifying K-channels was found to be completely inhibited in the presence of 500 nM capsaicin (Park, K. *et al.*, 2003), suggesting a mechanism by which capsaicin could enhance gustatory responses of taste receptor cells. In a similar set of experiments, 30 μM capsaicin was found to inhibit both the peak inward current and the peak outward current by 20% and 30%, respectively (Costa, R. M. *et al.*, 2005). Attenuation of the voltage-sensitive inward current would result in decreased sensitivity to any gustatory stimulus. Interestingly, support for a non-TRPV1-mediated mechanism was observed in a behavioral experiment where the preference for sucrose exhibited by TRPV1-knockout mice was abolished in the presence of capsaicin (Costa, R. M. *et al.*, 2005).

Substance P and CGRP are released from the peripheral terminals of nociceptive nerve endings in response to an activating noxious stimulus (Holzer, P., 1998). The close proximity of nociceptive free nerve endings to taste receptor cells suggests that peptides released might modulate gustatory signaling. To specifically address the direct effect of neuropeptides on gustatory signaling, Simon S. A. *et al.* (2003) recorded chorda tympani taste responses in the presence and

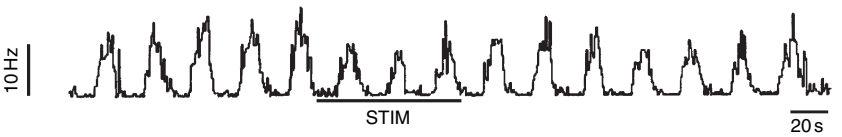

Figure 7 Peripheral trigeminal modulation of taste nerve activity. Shown are responses (in PSTH format) of a single chorda tympani fiber to repeated application of 0.1 M NaCl to the tongue, without and during electrical stimulation of the lingual nerve (0.5 ms biphasic pulses at 15 Hz and 5 V). Note the depressant effect of lingual nerve stimulation on tastant-evoked responses. From Wang, Y., Erickson, R. P., and Simon, S. A. 1995. Modulation of rat chorda tympani nerve activity by lingual nerve stimulation. J. Neurophysiol. 73, 1468–1483, figure 8B, with permission.

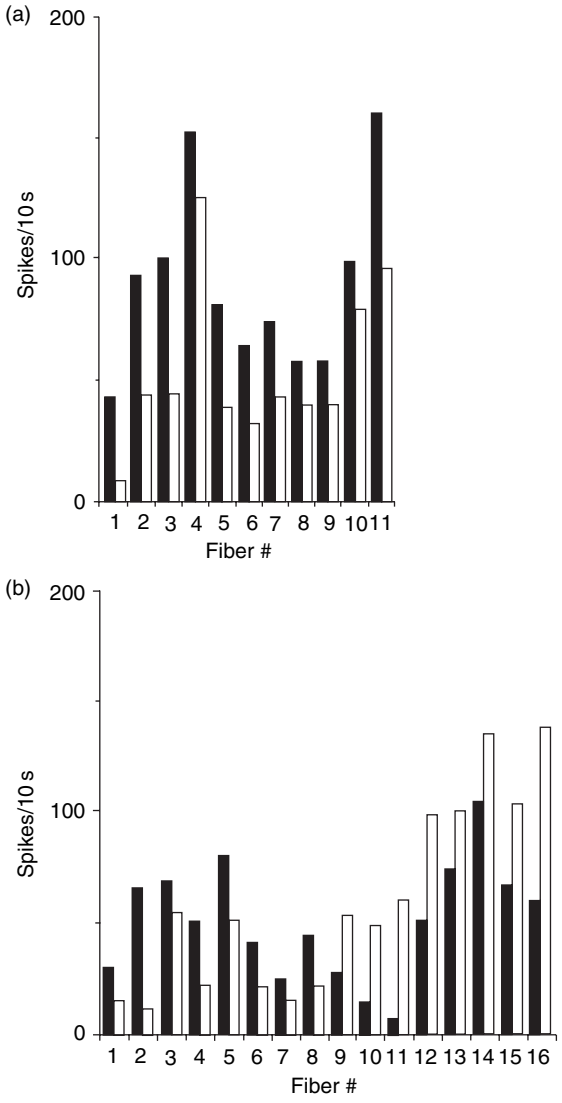

Figure 8 Capsaicin modulation of taste nerve responses. Graphs plot the responses of single N-type (a: responsive to sodium salts) and E-type (b: broadly responsive to cations) chorda tympani fibers. Filled bars show responses to 100 mM NaCl. Open bars show responses to 100 mM NaCl plus 100 ppm capsaicin. Note that responses of N-type fibers were depressed in the presence of capsaicin, while responses of some E-type fibers were depressed and others enhanced in the presence of capsaicin. From Osada, K., Komai, M., Bryant, B. P., Suzuki, H., Goto, A., Tsunoda, K., Kimura, S., and Furukawa, Y. 1997. Capsaicin modifies responses of rat chorda tympani nerve fibers to NaCl. Chem. Senses 22, 249–255, figure 4, with permission.

absence of substance P and CGRP. Whole-nerve recordings in response to lingual NaCl, HCl, quinine HCl, and sucrose were made from the chorda tympani of rats. Simultaneously, substance P or CGRP was infused into the ipsilateral lingual artery. Infusion of CGRP reduced the chorda tympani response to NaCl and HCl to about 80% of preinfusion levels (Figure 9). Importantly, these effects were shown to be independent of any vasoactive or thermal change induced by neuropeptide infusion. Conversely, substance P injection had no noticeable effect on NaCl or HCl when injected at concentrations that did not induce vasodilation or increased lingual temperature. In addition, neither substance P nor CGRP had any apparent effect on sucrose- or quinine-evoked responses. However, for these two taste responses, methodological limitations were thought to have mitigated the reliable detection of possible neuropeptide effects.

Results from central gustatory recordings corroborate the existence of peripheral interactions between the trigeminal and gustatory systems. Responses to sucrose, quinine HCl, monosodium glutamate, NaCl, and citric acid recorded from taste cells in the NTS were shown to be significantly suppressed following prolonged (7 min) lingual capsaicin (100 μM) application (Figure 10) (Simons, C. T. *et al.*, 2003a). Across all tastants, capsaicin suppressed the evoked response to approximately 57% of precapsaicin levels. Interestingly, the same level of capsaicin suppression was observed after bilateral trigeminal ganglionectomy, indicating that an intact trigeminal pathway is not required for capsaicin attenuation of taste responses (Simons, C. T. *et al.*, 2003a).

Anatomical studies further support a peripheral effect of capsaicin (Simons, C. T. *et al.*, 2003a). In addition to the direct effects of neuroactive peptides mentioned previously, substance P and CGRP have potent vasoactive properties that induce changes in the permeability of the vascular wall leading to a localized inflammatory response including plasma extravasation and edema. Tests for plasma extravasation typically involve the systemic injection of dye into the bloodstream followed by a noxious stimulus. When plasma extravasation occurs, dye that has leaked out of the vasculature is found to have stained surrounding tissue. Following lingual capsaicin application, plasma extravasation was found to be localized to the intragemmal space of taste papillae (Figure 11), and this effect was seen in both intact and ganglionectomized animals. This finding provides additional evidence that neuropeptides act in close proximity to taste receptor cells and suggests that edema localized to the taste bud may also play a role in capsaicin-induced taste suppression.

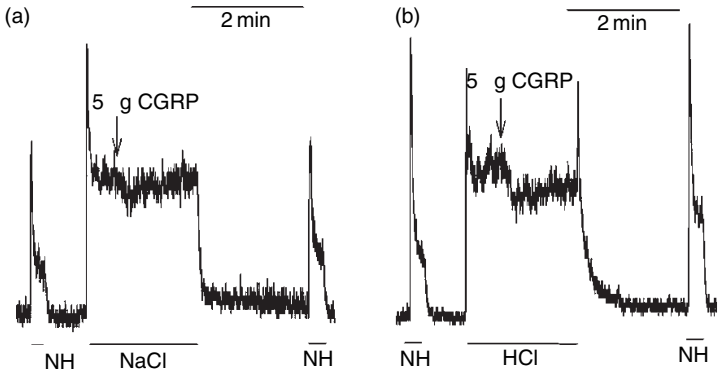

Figure 9 Depressant effects of calcitonin gene-related peptide (CGRP) on chorda tympani fiber responses to tastants. Shown are the effects of lingual artery perfusion of 5 μg CGRP in 100 μl KH buffer (arrows). Responses to 0.1 M NH_4Cl bracket each trial. (a) CGRP (at arrow) decreased the tonic responses to 0.1 M NaCl. (b) CGRP (arrow) decreased response to 10 mM HCl. From Simon, S. A., Liu, L., and Erickson, R. P. 2003. Neuropeptides modulate rat chorda tympani responses. Am. J. Physiol. (Regul. Integr. Comp. Physiol.) 284, R1494–R1505, figure 7.

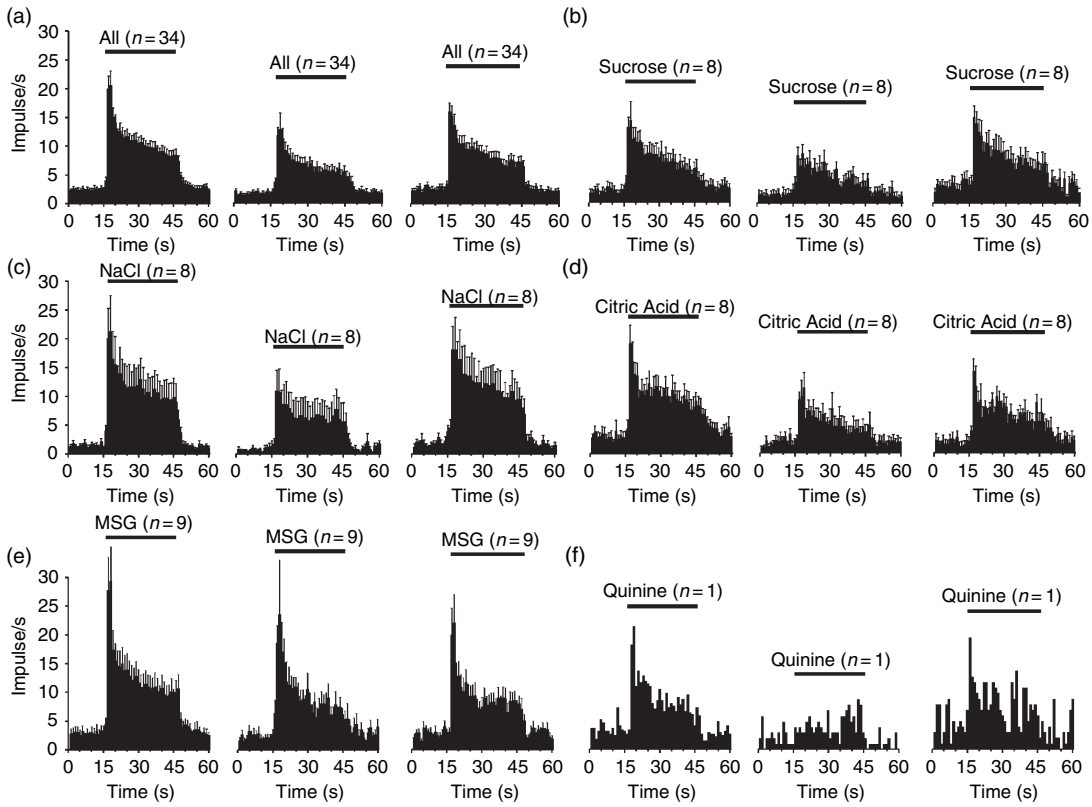

Figure 10 Suppression of tastant-evoked responses of nucleus of the solitary tract (NTS) units by oral capsaicin. Each triad of panels shows averaged peristimulus–time histograms (PSTHs) of NTS unit responses to the indicated tastant, before capsaicin (left PSTHs), immediately after cessation of capsaicin (middle PSTHs), and 12 min after cessation of capsaicin (right PSTHs). Horizontal bars indicate 30 s duration of tastant stimulus. Error bars indicate SEM. (a) Data from all 34 units were pooled to show averaged responses to the best tastant. Note suppression of response (middle panel; to 57%) immediately after capsaicin with recovery (right panel). (b) Sucrose. Note suppression (middle panel; to 63%) immediately after capsaicin with recovery (right panel). (c) NaCl. Note suppression (middle panel; to 44%) immediately after capsaicin with recovery (right panel). (d), Citric acid. Note suppression (middle panel; to 50%) immediately after capsaicin with partial recovery (right panel). (e) Monosodium glutamate (MSG). Note suppression (middle panel; to 73%) immediately after capsaicin with little or no recovery (right panel). (f), Quinine; individual example showing that the response of the unit to quinine (left panel) was depressed immediately after capsaicin (middle panel) with recovery (right panel). From Simons, C. T., Boucher, Y., and Carstens, E. 2003a. Suppression of central taste transmission by oral capsaicin. J. Neurosci. 23, 978–985, figure 2, with permission.

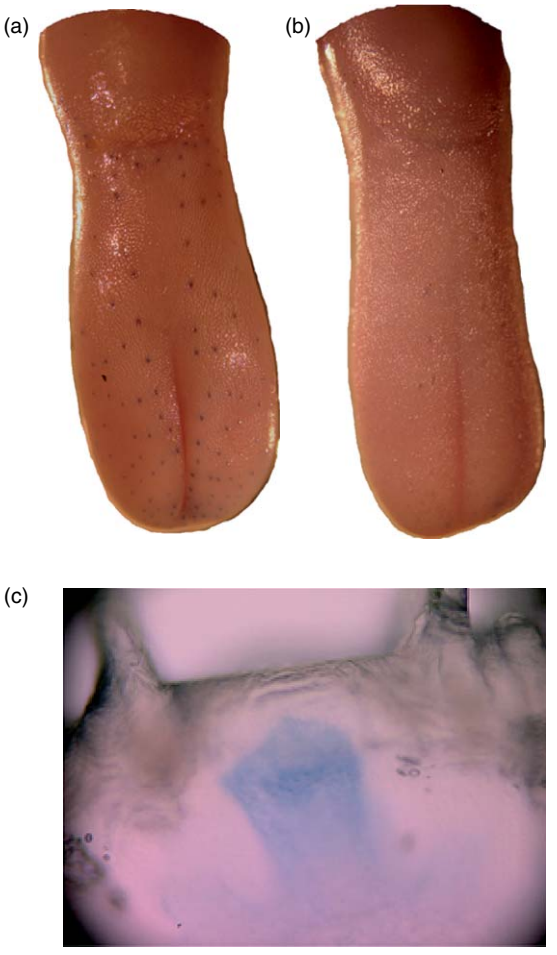

Figure 11 Capsaicin-induced plasma extravasation. (a) Photograph of rat tongue treated previously with topical capsaicin. Note accumulation of blue dye within taste papillae across the lingual surface. (b) Photograph of rat tongue pretreated with ethanol. Note absence of punctuate dye extravasation. (c), Photomicrograph of section through fungiform papillae (100× magnification). The black arrowhead indicates the dorsal lingual surface, whereas the white arrowhead shows a filliform papilla. Note that blue dye accumulates within the taste bud, with little or none in surrounding tissues. From Simons, C. T., Boucher, Y., and Carstens, E. 2003a. Suppression of central taste transmission by oral capsaicin. J. Neurosci. 23, 978–985, figure 6, with permission.

4.18.4.2 Central Interactions – Nucleus of the Solitary Tract

Several investigators have found that second-order neurons located in the caudal portion of the gustatory nucleus respond not only to sapid stimuli but also to touch and temperature (Ogawa, H. and Hayama, T., 1984; Ogawa, H. *et al.*, 1984; 1988; Halsell, C. B. *et al.*, 1993; Travers, S. P. and Norgren, R., 1995). Although the chorda tympani nerve is well known to respond to tastants as well as to mechanical and thermal stimuli (Ogawa, H. *et al.*, 1968; Robinson, P. P., 1988), these findings nevertheless give rise to the possibility that gustatory and somatosensory (including nociceptive) information converge onto cells located within the gustatory NTS. Anatomic evidence additionally provides support. Primary afferent trigeminal fibers have been shown to send collateral branches into the NTS (Beckstead, R. M. and Norgren, R., 1979), and second-order neurons originating in Vc similarly project onto the same region (Davis, B. J. and Kream, R. M., 1993). Moreover, trigeminal afferent fibers projecting to the NTS contain the neuromodulator substance P (South, E. H. and Ritter, R. C., 1986), and dense neurokinin 1 (substance P receptor) labeling has been observed in the same dorsomedial and dorsolateral subnuclei (Davis, B. J and Smith, D. V., 1997). Physiological findings confirm that substance P has a modulatory effect on gustatory cellular activity. Whole-cell patch-clamp recordings in rat brainstem slices showed the intrinsic activity of NTS units was influenced by the application of substance P (0.1–4 μM) to the bathing medium (King, M. S. *et al.*, 1993). Indeed, substance P induced a transient (~7 min) depolarization in 70% of the tested neurons that was accompanied by an increase in the input resistance. In contrast, only 4% of neurons exhibited a hyperpolarization following substance P exposure. These findings suggest that substance P has primarily an excitatory effect that is mediated by the closure of ion channels. Similar results were obtained from whole animal recordings where microinjection of substance P into the hamster NTS was found to modulate the responses to electrical or NaCl stimulation of the tongue (Davis, B. J and Smith, D. V. 1997). In 60% of the neurons tested, substance P injection increased the activity evoked by electrical stimulation. In the remaining 40%, substance P substantially reduced (to approximately 50%) the electrically evoked response. Correspondingly, nearly 50% of the NaCl-evoked responses were increased following injection of substance P into the NTS. However, in contrast to the electrical stimulus, only 9% of NaCl-evoked responses were inhibited by substance P. Thus, substance P appears to be a potent and varied modulator of central gustatory cells, although it is still speculative this effect is mediated by trigeminal activity.

Dense innervation of the NTS by inhibitory GABAergic and opioidergic neurons (Lynch, W. C.

et al., 1985; Davis, B. J, 1993; Davis, B. J. and Kream, R. M., 1993) suggests another mechanism of inhibitory modulation. Noxious stimuli directed at the oral cavity could activate trigeminal nociceptors that further excite inhibitory interneurons to directly suppress tastant-evoked activity in NTS.

Functional studies directly testing the hypothesis that trigeminal activity modulates central gustatory responses have recently been completed (Boucher, Y. *et al.*, 2003; Simons, C. T. *et al.*, in press). Single-cell gustatory responses were recorded from rats before and after trigeminal ganglionectomy (Boucher, Y. *et al.*, 2003). Ganglioectomy *per se* did not modulate taste responses, suggesting that trigeminally mediated excitatory or inhibitory processes are not tonically active. However, with simultaneous electrical activation of the central cut end of the mandibular nerve, 64% of gustatory responses were modulated relative to prestimulation levels. Indeed, approximately 21% of the gustatory responses were inhibited by simultaneous mandibular nerve stimulation, whereas 43% of the responses were enhanced (Boucher, Y. *et al.*, 2003). Consistent with a peripheral mode of suppression, central gustatory responses were attenuated when the peripheral cut end of the mandibular nerve was stimulated.

Nicotine activation of trigeminal afferents has a similar effect (Simons, C. T. *et al.*, in press). Topical application of nicotine to the tongue for a period of 4 min suppressed taste responses recorded in NTS. This effect was dose dependent. Whereas low nicotine concentrations (0.84 mM) had no effect, higher doses (8.4 mM or 600 mM) suppressed taste-evoked responses to 54% and 27%, respectively. The attenuation was nearly equal for all taste qualities. Mecamylamine was shown to reduce the nicotine's suppressive effect of taste responses, suggesting the involvement of nicotinic cholinergic receptors. Interestingly, following bilateral ganglionectomy, nicotine application had no effect on taste responses, indicating that nicotine suppression of taste occurs centrally and is mediated through the trigeminal system. This is in marked contrast to capsaicin which was shown to have a peripheral mechanism of suppression.

4.18.4.3 Cognitive Interactions

In addition to the possible peripheral and central mechanisms discussed above, high-level interactions occurring in the cortex might contribute to the effect of oral irritants on taste perception. The convergence of somatosensory and taste pathways into the insular and orbitofrontal cortex provides the neural substrate for these interactions to occur (Cerf-Ducastel, B. *et al.*, 2001). Several studies have identified neurons in the orbitofrontal cortex that respond to gustatory as well as to somatosensory stimuli (Rolls, E. T. *et al.*, 1999; 2003; Verhagen, J. V. *et al.*, 2003; Kadohisa, M. *et al.*, 2004; 2005). In particular, neurons were identified that responded to taste but also to the texture (Rolls, E. T. *et al.*, 1999; 2003; Verhagen, J. V. *et al.*, 2003) and temperature (Kadohisa, M. *et al.*, 2004; 2005) of a stimulus as well as the presence of capsaicin (Kadohisa, M. *et al.*, 2004; 2005). These studies indicate that areas involved in high-level stimulus processing can be modulated by a variety of multimodal inputs to impact both perception and palatability.

There are several possible ways that higher-order somatosensory–taste interactions can result in altered perceptual responses. It is well known that attention is a primary determinant of perception (Marks, L. E. and Wheeler, M. E., 1998; Driver, J. and Frackowiak, R. S., 2001). Attending to a stimulus brings it into the consciousness where it can be evaluated and processed. It is plausible, under some paradigms, that the presence of oral irritation draws attention away from the gustatory stimulus such that it is perceived as less intense. Similarly, context effects have often been shown to impact perceived stimulus intensity. Any evaluation of stimulus strength is made in the context of other stimuli. When a given stimulus is evaluated in the presence of a stronger stimulus, intensity of the first stimulus is often reported as much less than when that same stimulus is evaluated alone or in the presence of a weaker stimulus. Changes to intensity judgments due to context have been explained by Parducci's range–frequency theory (Parducci, A., 1965). Two studies assessed the context effect in regard to the mechanism by which trigeminal irritants modulate taste perceptions (Gilmore, M. M. and Green, B. G., 1993; Simons, C. T. *et al.*, 2002).

In one study (Simons, C. T. *et al.*, 2002), context effect was minimized by using a half-tongue methodology in which capsaicin was applied unilaterally but taste intensity was evaluated bilaterally. In this condition, context effect would be expected to affect perceived taste on both sides equally not just the side receiving capsaicin pretreatment (Simons, C. T. *et al.*, 2002). Moreover, context effect is a generalized phenomenon and would not be expected to impact only specific taste qualities. However, these results were not observed. In fact, capsaicin irritation suppressed

only the perceived intensity of sweetness, bitterness, and umami sensations. Another study noted that context effect plays a role in the suppression of salt and sour tastes following zingerone desensitization as well as playing lesser role following capsaicin desensitization (Gilmore, M. M. and Green, B. G., 1993). Thus, psychological mechanisms including attention and context effect may contribute to the chemesthetic suppression of taste observed both anecdotally and experimentally, and this is a factor that should be controlled for.

Masking is another mechanism by which the presence of oral irritants might impact the perception of gustatory stimuli. Masking is a phenomenon that occurs when the presence of one stimulus obscures the presence of another. In most cases, masking can be achieved simply by increasing the intensity of a second stimulus. In the food and beverage industry, off-notes related to a particular ingredient can be masked by increasing the concentration of a more desirable ingredient. Thus, the presence of a bitter stimulus is often masked by increasing the level of sucrose or other palatable substance. There are limitations as to how effective masking can be. For instance, it is often difficult to mask very intense stimuli. Additionally, often masking agents have a concentration at which they are most effective. Going beyond that level can result in additional undesirable attributes. Capsaicin might serve as a masking agent. The perception of an irritating sensation could mask the sensation evoked by gustatory stimuli. The convergence of taste and somatosensory information in the orbitofrontal cortex (Kadohisa, M. *et al.*, 2004; 2005) provides a mechanism by which a chemoirritants can modulate gustatory information. However, as with context effects, masking is a general phenomena, and it would not be expected to impact only select taste qualities.

4.18.5 Perspectives

The study of the chemical senses is beginning to flourish. In particular, chemesthesis research is attracting the attention of a greater number of investigators. Light is beginning to be shed on questions that were unresolved just a few years ago. However, to further the knowledge of chemesthesis, a multidisciplinary approach using genetic, molecular, physiological, and perceptual methods will be needed. Unlike many sensory systems, chemesthetic information appears to be transmitted relatively faithfully from the periphery to higher centers of the brain. This provides an ideal opportunity to link perceptual endpoints to the neural and molecular correlates that drive them. As the era of molecular biology continues to unfold, undoubtedly additional receptors will be identified that contribute to chemesthetic perception. It will be imperative to understand how these receptors are distributed across trigeminal neurons and how they contribute to the sensations elicited by chemical stimuli. In addition, further studies are needed to delineate whether qualitative differences exist between the sensations elicited by different chemoirritants. The cross-modal interactions occurring between chemesthesis and taste are deserving of more attention. It is clear that multiple mechanisms contribute to the ability of oral irritants to suppress gustatory processing. However, to date, only a few of the many chemesthetic stimuli have been evaluated for effects on taste. It will be interesting to determine whether taste suppression is a phenomenon common to all oral irritants or, alternatively, if only select compounds have this capacity.

Glossary

complex trait A trait influenced by multiple factors, including effects of genes, environment, and their interactions.

congenic strain A strain that is identical to one of the progenitor inbred strains (inbred partner or background strain) except for a particular locus of interest that originates from the other progenitor strain (donor strain). Traditional congenic strains are produced through a series of at least 10 lineal backcrosses. Marker-assisted selective breeding of congenic strains (speed congenics) requires a smaller number of backcross generations.

conserved synteny Correspondence in order of chromosomal locations of orthologous genes in different species.

inbred strain A strain that has been bred using brother–sister matings for at least 20 consecutive generations. Same-sex individuals within an inbred strain are considered to be ~99% identical genetically.

haplotype Haploid genotype; a combination of linked alleles at an individual chromosome; may refer to a set of linked genes or to a set of sequence variants within a gene.

locus A location in the genome. It may correspond to a gene, an anonymous DNA segment (marker), or a genomic region linked to a phenotypical variation (qualitative or quantitative trait locus).

ortholog Genes or proteins in different species that have similar sequences, which suggests that they have originated from a common ancestral gene.

paralog Genes in the same species with similar sequence, which suggests that they originated from a common ancestral gene.

phenotype The observable characteristics of an organism, as determined by both genetic makeup and environmental influences.

recombinant inbred strains A set of independently derived strains, all of which originate from

the same two inbred progenitor strains. The two inbred progenitor strains are outcrossed to produce F_1 hybrids, which are intercrossed to produce F_2 hybrids, followed by consecutive generations of brother–sister matings. After 20 generations of brother–sister mating, mice within each recombinant inbred strain are genetically nearly identical.

segregating cross A cross between inbred strains, in which alleles of polymorphic markers or genes segregate among subgroups of the cross with different genotypes. Commonly produced segregating crosses are hybrids of the second filial (F_2) or a backcross (N_2) generation.

4.19.1 Taste Is a Complex Trait

Behavioral genetic approaches have been instrumental in the discovery of genes that influence taste phenotypes. The investigation of genetic bases of taste began early in the twentieth century with the description of human differences in sensitivity to the bitter-tasting chemical phenylthiocarbamide (PTC) (Fox, A. L., 1931; 1932). In the years following this discovery, behavioral genetic approaches conducted predominately in mice identified considerable variation in taste responses among inbred strains. Chromosomal mapping of genetic loci influencing preferences for sweet- and bitter-tasting stimuli led to the identification of families of G-protein-coupled receptors (GPCR) for sweet and bitter taste. However, the search for genes influencing taste function is not necessarily limited to receptors. Situated at the beginning of the alimentary canal, the gustatory system is a key player in homeostatic systems dealing with both fluid and food intake. In fact, taste and feeding are linked in terms of reciprocal connectivity between brain regions, and taste detection has been shown to be heavily modulated by postingestive feedback, including neural and hormonal factors (e.g., Scott, T. R., 2001; Bloomgarden, Z. T., 2006). Additionally, evidence indicates that taste sensitivity is modifiable by environmental factors such as diet and experience (Duffy, V. B. and Bartoshuk, L. M., 2000; Tichansky, D. S. *et al.*, 2006). This interactivity implies that taste sensitivity is a complex trait, and as such taste-related behavior phenotypes are likely to be determined by multiple genes and factors (Figure 1). This review will focus primarily on the study of rodent taste behavior genetics, as human genetic approaches are reviewed elsewhere (Chapter Propylthiouracil (PROP) Taste). However, an evolutionary perspective on taste receptor genes will include both vertebrate and invertebrate species.

Traditionally, the five major taste qualities have been described using terms that reflect human perceptual experience (sweet, salty, bitter, sour, and umami). Although there are many studies indicating that the mechanisms underlying perception of different taste qualities are similar in humans and nonhuman species, one should use caution when applying human descriptors to animal sensory function. It is perhaps more accurate to describe taste quality perception by nonhuman animals using chemical names of taste stimuli (e.g., sodium taste or sucrose-like taste), but for brevity the human descriptors are used throughout this review.

4.19.2 Genetic Approaches to Taste Behavior

4.19.2.1 Assessing Taste Behavior

Taste ability includes multiple aspects such as quality, intensity, and hedonic value. In addition, taste behavior may be influenced by nongustatory sensory factors such as olfaction and somatosensation. Early studies of human genetic variation of taste sensitivity concentrated on either responses to a single concentration of a stimulus (i.e., tasters vs. nontasters of PTC) or measurement of detection thresholds (Harris, H. and Kalmus, H., 1949; Wooding, S., 2006). More recent studies have utilized psychophysical methods such as suprathreshold magnitude estimation (Bartoshuk, L. M. *et al.*, 1994) to evaluate additional aspects of taste perception. In rodents, the majority of behavioral genetic studies have been conducted using 48 h two-bottle preference test, where an animal is presented with two bottles in the home cage, one containing water, and one containing a taste solution. After 24 h, the position of the bottles is switched to control for side preference (Richter, C., 1932). In these tests, the taste quality and intensity of the stimulus are inferred based

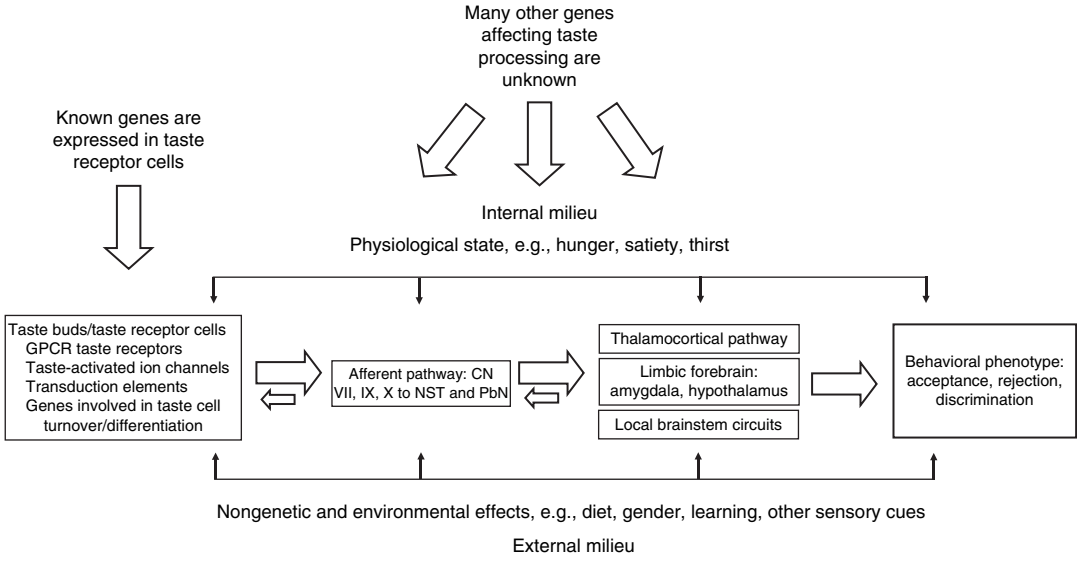

Figure 1 Components of the taste system and its associated genes. The search for the genetic basis of taste has primarily focused on taste receptors and other components of the taste signaling pathway expressed in peripheral taste receptor cells, and their relationship to taste behavior phenotypes. Other genes must play a role in complex interactions between peripheral mechanisms, brain taste centers, and behavioral outcomes. All of these steps in taste processing are subject to modulation by factors associated with the internal and external milieu, including physiological systems involved in food and fluid intake, and by other, nongenetic factors such as diet, learning, and exteroceptory cues like odors or visual stimuli. CN, cranial nerve; NST, nucleus of the solitary tract; PbN, parabrachial nucleus.

on level of avoidance or preference for the solution bottle. Such tests are relatively simple to conduct, and offer a considerable advantage in that one may conduct simultaneous testing of large groups of animals that are required for the genetic analysis. Tests involving multiple stimulus bottles are also useful (Tordoff, M. G. and Bachmanov, A. A., 2003). However, behavior over this relatively long time frame may be influenced not only by an animal's perception of a stimulus, but also by postingestive consequences. Taste-salient, brief-access tests minimize postingestive cues by restricting sampling times to short durations (<30 s). Such tests have been recently modified for use in high-throughput screening of taste function in mouse populations (Boughter, J. D., Jr. *et al.*, 2002; Glendinning, J. I. *et al.*, 2002). Behavioral test methods for animals are reviewed extensively in Chapter Behavioral Analysis of Taste Function in Rodent Models.

4.19.2.2 Behavioral Genetic Techniques

The goal of behavioral genetics is to understand how genes influence individual differences. Usually, a starting point for discerning genetic effects on behavior in rodents is the use of inbred strains. After 20 generations of inbreeding, same-sex individuals within a given strain are considered to be ~99% identical genetically. When individuals from multiple inbred strains are compared on a particular behavior or phenotype, the mean difference among these strains means is considered to be due to genetic factors. Commonly used strains in biomedical research include C57BL/6 (B6), DBA, 129, and BALB. Indeed, early studies with inbred mice indicated substantial strain differences in solution intake for various taste qualities (McClearn, G. E. and Rodgers, D., 1959; 1961; Hoshishima, K. *et al.*, 1962). Since then, inbred strains have been extensively characterized with regards to taste ability using not only intake tests, but also taste-salient behavioral tasks, taste nerve and central nervous system (CNS) physiology, and anatomical methods (e.g., Ninomiya, Y. *et al.*, 1984; Shingai, T. and Beidler, L. M., 1985; Ninomiya, Y. and Funakoshi, M., 1989; Kachele, D. L. and Lasiter, P. S., 1990; Lush, I. E., 1991; Eylam, S. and Spector, A. C., 2004; Inoue, M. *et al.*, 2004a; Boughter, J. D., Jr. *et al.*, 2005; McCaughey, S. A., 2007). Inbred strains of rats have not been used as commonly, although rat strains differ in salt and sweet taste responses (Sollars, S. I. *et al.*, 1990; Goodwin, F. L. and Amit, Z., 1998).

Differences between strains serve as the starting point for genetic mapping studies. Using Mendelian

crosses of parental strains (i.e., F_1 and F_2 hybrids, and backcrosses) the investigator may estimate the relative size and number of genetic factors contributing to the behavior (Figure 2). Individuals from a segregating generation such as F_2 can be both phenotyped with respect to taste behavior, and genotyped using a set of genetic markers such as single nucleotide polymorphisms (SNPs). Significant association between phenotype and marker results in the identification of qualitative or quantitative trait loci (QTL) that pinpoint regions of the genome where genes influencing the trait of interest reside. For example, QTL studies conducted in an F_2 cross of B6 (high sweetener preferring) and 129 (low preferring)

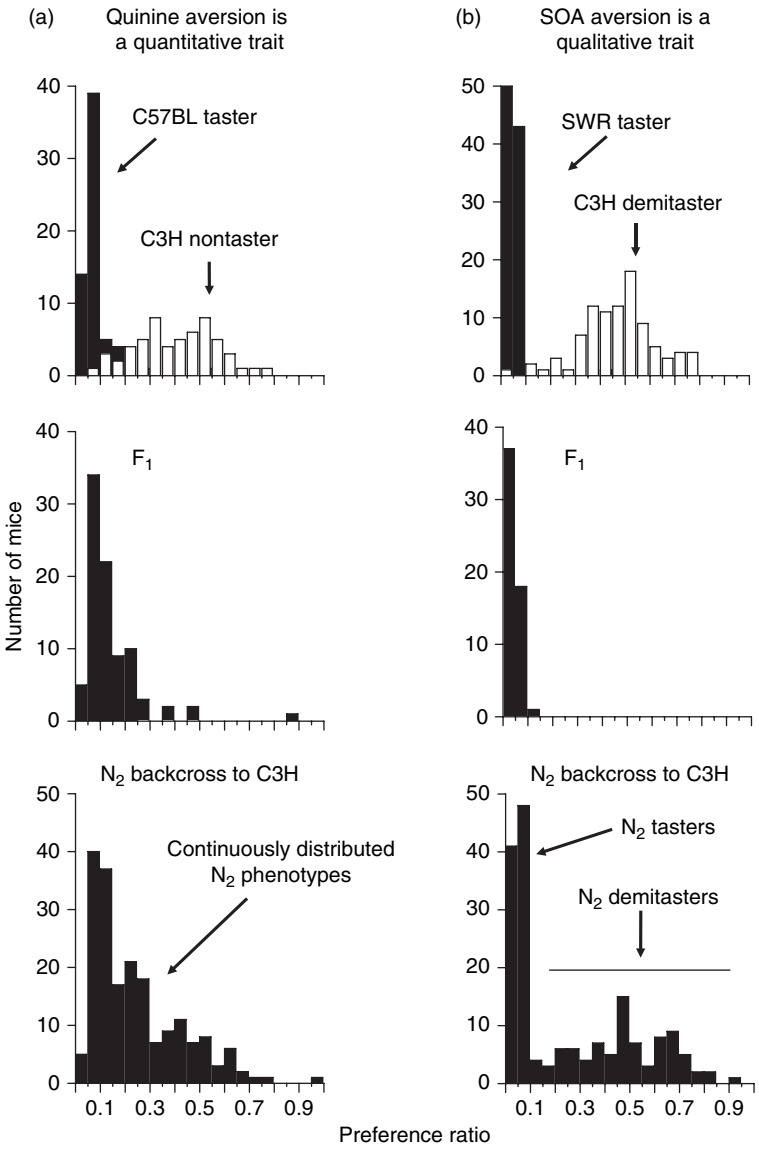

Figure 2 Examples of quantitative and qualitative traits for bitter taste aversion. Graphs show individual distributions of preference ratios for quinine (a) or sucrose octaacetate (SOA) (b) solutions. For quinine (a), there is overlap in the distributions between C57BL/6 (taster) and C3H/HeB (nontaster) progenitor inbred strains. An F_1 generation consists primarily of phenotypic tasters, whereas the N_2 backcross to C3H is comprised of a continuous distribution of phenotypes ranging from taster to nontaster. This continuous distribution is consistent with control by more than one quantitative trait locus. For SOA (b), there is almost no overlap in the distributions of SWR (taster) and C3H (demitaster) progenitor inbred strains. The F_1 distribution is comprised of phenotypic tasters. The N_2 backcross distribution is bimodal, consisting of about half tasters, half demitasters. Unlike the case for quinine, this distribution is consistent with expectations from a single locus model. SOA aversion is therefore a qualitative trait. Data from Boughter J. D. Jr., *et al*. (1992) and Boughter J. D. Jr., and Whitney G. (1995).

mouse strains demonstrate loci linked to both behavioral and physiological responses to sweeteners (Inoue, M. *et al.*, 2004b). Recombinant inbred (RI) strains (Figure 3) have also been used to identify QTLs influencing behavioral or neural phenotypes, including the frequently used BXD set, derived from B6 and DBA/2 mice (Peirce, J. L. *et al.*, 2004). Notably, BXDs have been used to map QTLs influencing sweet and bitter taste in mice (Lush, I. E. and Holland, G., 1988; Nelson, T. M. *et al.*, 2005). Finally, congenic strains (Figure 4) have been used extensively in taste behavioral genetic research (Whitney, G. *et al.*, 1989; Boughter, J. D., Jr. and Whitney, G., 1995; Bachmanov, A. A. *et al.*, 2001a; Li, X. *et al.*, 2001). A congenic strain is one that is identical to a progenitor inbred strain except for the substitution of a particular locus of interest (Flaherty, L., 1981). This is accomplished through a series of (at least 10) lineal backcrosses. The newly created mice are used to evaluate an allelic variant against a particular strain background. For example, 129.B6 congenics (created from 129P3 and B6 mice) were used to localize the *Sac* locus influencing sweetener preference in mice (Li, X. *et al.*, 2001).

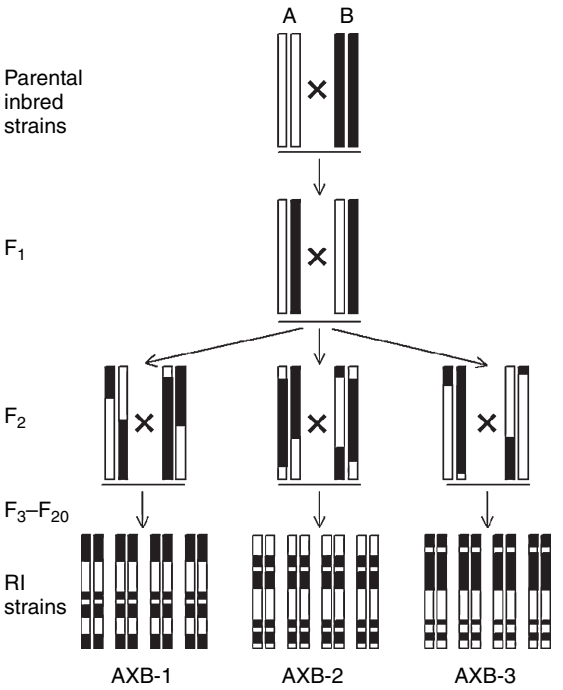

Figure 3 Production of recombinant inbred (RI) strains. A pair of homologous autosomes is shown in different generations of RI strains production. Genetic material of two hypothetical progenitor inbred strains, A and B, is shown in white and black respectively. Recombinant chromosomes (combining parts from both progenitor strains) are first observed in the F_2 generation. Randomly chosen F_2 mice are mated, and their offspring is maintained by brother–sister mating for at least another 18 generations. In the subsequent generations of breeding, additional chromosomal recombinations occur, and mice of each RI strain become genetically more similar. After 20 generations of brother–sister mating, mice within each RI strain are genetically nearly identical (illustrated by chromosomal pairs of four mice from thee hypothetical RI strains).

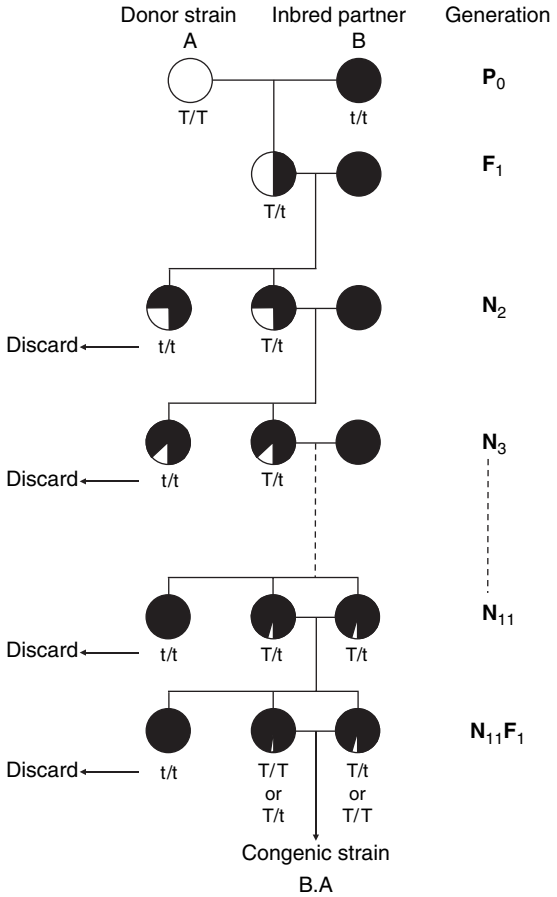

Figure 4 Backcross protocol for congenic strain development involving transfer of an autosomal dominant taster allele T from a donor strain (strain A; white circle) onto the genomic background of an inbred partner (strain B; black circle) with a recessive nontaster allele t. F_1 heterozygote offspring from the parent strains are mated to mice from the partner strain. Only phenotypic taster offspring (T/t) from subsequent generations are selected for backcrossing to the partner strain. With each backcross generation, one-half of the remaining genetic material from the donor strain is lost, except for material closely linked on the chromosome bearing the locus of interest. By generation N_{11}, the introgressed chromosome segment is isolated on a ~99% genomic background from the partner strain. Tasters from generation N_{11} and subsequent generations are sib intercrossed.

4.19.3 Bitter Taste

A large and diverse array of molecules evoke the sensation of bitterness, and the ability to detect and avoid these stimuli is assumed to have evolved as a mechanism to prevent ingestion of toxins (Spielman, A. I. *et al.*, 1992). In fact, a strong correlation exists in the animal kingdom between bitter sensitivity and tolerance to toxic compounds (Glendinning, J. I., 1994). It has long been appreciated that there is substantial variation among mouse strains in regard to intake and aversion of bitter-tasting compounds. The discovery of genetic loci influencing bitter sensitivity led to the identification of a family of GPCR genes, dubbed *Tas2r*s. These receptors are characterized by a short N-terminus with a potential transmembrane ligand-binding domain. To date, about 25 human and 36 mouse bitter taste receptor genes have been identified, although only a handful have known ligands.

4.19.3.1 Phenylthiocarbamide Taste in Man and Mouse

Variation in taste sensitivity for the bitter goitrogenic compound PTC is a classic example of an inherited trait in humans. It has been the source of much genetic and sensory research since the 1930s (see Chapter Propylthiouracil (PROP) Taste). It is now known that up to 85% of the variation in PTC sensitivity among humans is accounted for by allelic variation of a single bitter taste receptor gene on chromosome 7q, dubbed *TAS2R38* (Kim, U. K. *et al.*, 2003; Kim, U. K. and Drayna, D., 2005). Spurred on by the early discovery of human variation in PTC sensitivity, investigators sought a parallel finding in animal models. There was some evidence for a PTC dimorphism in chimpanzees (Fischer, R. A. *et al.*, 1939), suggesting that taste polymorphisms were not restricted to humans. Richter C. and Clisby K. H. (1941) reported individual variation in PTC avoidance thresholds of rats, although the genetic analysis of this was not pursued. Mice from a BALB strain displayed greater aversion of PTC in two-bottle tests than mice from other strains, including B6, although this difference required 10–12 consecutive days of testing to develop (Klein, T. W. and DeFries, J. C., 1970; Whitney, G. and Harder, D. B., 1986a). Several intercross and backcross generations created from BALB and B6 strains yielded segregation ratios consistent with phenotypic control by a single autosomal locus, with a dominant taster allele. It was suggested that this effect reflects other variables in addition to sensory ability, such as sensitivity to postingestive effects of PTC, which is extremely toxic to mice. A direct comparison of intake tests and brief-access procedures demonstrated that differential avoidance of PTC among inbred strains depends on the amount of stimulus consumed, and not necessarily on immediate orosensory or taste cues (Nelson, T. M. *et al.*, 2003). Furthermore, PTC has been shown to be nearly as effective as LiCl in serving as the unconditioned stimulus in a conditioned taste aversion (CTA) experiment (St. John, S. J. *et al.*, 2005). Although sensitivity to PTC and the chemically related compound 6-*n*-propylthiouracil (PROP) is highly correlated among human subjects, aversions to these compounds do not correlate among mice (Barnicot, N. *et al.*, 1951; Whitney, G. and Harder, D. B., 1994). In summary, an ortholog to the human PTC receptor *TAS2R38* has not yet been described in mice, a finding perhaps not surprising in light of species-specific differences in the bitter taste gene family (Shi, P. *et al.*, 2003).

4.19.3.2 Genetics of Taste Responses to Other Bitter Compounds in Mice

The genetic basis of differences in taste sensitivity to other bitter compounds has been studied throughout the last several decades. Inbred mouse strains have been found to differ in aversion to a large number of both toxic and nontoxic bitter stimuli, including (but not limited to) quinine, strychnine, acetylated sugars, $MgCl_2$, cycloheximide, denatonium benzoate, isohumulone, quinine, and sucrose octaacetate (SOA) (Warren, R. P. and Lewis, R. C., 1970; Lush, I. E., 1981; 1982; 1984; 1986; Lush, I. E. and Holland, G., 1988; Whitney, G. and Harder, D. B., 1994; Bachmanov, A. A. *et al.*, 1996a; Boughter, J. D., Jr. and Whitney, G., 1998; Nelson, T. M. *et al.*, 2003). Aversion of the acetylated sugar SOA among mice is predominantly due to variation at a single qualitative trait locus, *Soa*, although SOA aversion may also be influenced by additional loci and environment. Aversion ratios among segregating generations of mice were consistent with variation at a single autosomal locus (*Soa*), with the taster allele dominant over either a demitaster (partial sensitivity) or nontaster allele (Figure 2; Lush, I. E., 1981; Whitney, G. and Harder, D. B., 1986b; Harder, D. B. *et al.*, 1992; Boughter, J. D., Jr. and Whitney, G., 1995). Results of both taste-salient brief-access behavioral tests and peripheral taste nerve physiology yielded concentration-by-concentration similarity with two-bottle data and

confirmed that the strain difference was gustatory in nature (Inoue, M. *et al.*, 2001a; Boughter, J. D., Jr. *et al.*, 2002). However, at least one other study has found evidence for polygenic control of SOA aversion (Le Roy, I. *et al.*, 1999). The aversion phenotype is subject to environmental modulation: unlike control tasters, taster mice raised on drinking water adulterated with a normally avoided concentration of SOA display only minimal avoidance of SOA in a two-bottle test with water (Harder, D. B. *et al.*, 1989). Unlike SOA avoidance, aversion to quinine and PROP in two-bottle tests has been demonstrated to be under polygenic control in segregating crosses or RI strains (Figure 2; Boughter, J. D., Jr. *et al.*, 1992; Bachmanov, A. A. *et al.*, 1996a; Harder, D. B. and Whitney, G., 1998). Interestingly, strain differences in intake of bitter-tasting drugs such as nicotine have been shown (Robinson, S. F. *et al.*, 1996; Butt, C. M. *et al.*, 2005), but it is not known whether these differences are related to taste or postingestive effects of these drugs.

4.19.3.3 Bitter Taste Loci and Receptors

Using a segregating cross of mice, Capeless C. G. *et al.* (1992) mapped a single locus influencing SOA sensitivity, *Soa*, to a region on distal mouse chromosome 6. This locus overlapped with the *Prp* genes encoding salivary proteins (Bachmanov, A. A. *et al.*, 2001a); although these genes were considered as candidates for the *Soa* locus, they have been shown not to influence SOA taste (Harder, D. B. *et al.*, 2000). Studies with RI and congenic strains linked aversion to a number of other bitter compounds, including quinine, cycloheximide, and PROP, to this same region (Lush, I. E. and Holland, 1988; Lush, I. E. *et al.*, 1995; Boughter, J. D., Jr. and Whitney, G., 1998; Blizard, D. A. *et al.*, 1999). Subsequent genome mining studies discovered a cluster of GPCR bitter taste receptor genes (*Tas2rs*) at this location (Adler, E. *et al.*, 2000; Chandrashekar, J. *et al.*, 2000; Matsunami, H. *et al.*, 2000). Recent characterization of the *Tas2r* receptor gene family in mice indicates 36 genes distributed into two clusters on distal chromosome 6 and one on chromosome 15, including 24 genes at the *Soa-Qui* locus that collectively comprise a large haplotype for bitter taste sensitivity (Wu, S. V. *et al.*, 2005; Nelson, T. M. *et al.*, 2005; Shi, P. *et al.*, 2003). It is likely that allelic variation of these receptors is responsible for phenotypical variation in sensitivity to different bitter tastants linked to the *Soa-Qui* locus.

Analysis of *Tas2r* sequences in strains of quinine taster (B6) and nontaster (DBA/2) mice reveals considerable variation across the *Tas2r* genes (Nelson, T. M. *et al.*, 2005). Among bitter receptors in the mouse, only two have been deorphanized thus far with respect to ligand, one responding exclusively to cycloheximide (encoded by the *Tas2r105* gene), the other to PROP and denatonium (encoded by *Tas2r108*) (Chandrashekar, J. *et al.*, 2000; Conte, C. *et al.*, 2006; Mueller, K. L. *et al.*, 2005). In contrast, several human T2R receptors (aside from T2R38) have been characterized with respect to ligand binding, including T2R16 which responds rather narrowly to a class of bitter chemicals known as β-glucopyranosides, T2R14 that responds to a variety of bitter stimuli, and T2R43 and T2R44 that respond to the bitter aftertaste of saccharin (Bufe, B. *et al.*, 2002; Behrens, M. *et al.*, 2004; Kuhn, C. *et al.*, 2004).

4.19.3.4 Evolution of the T2R Receptors

The study of taste receptor gene evolution has provided key insights into the dynamic process of adaptation of different species to their feeding ecology and environment. Invertebrates such as insects possess aversive responses to bitter-tasting or deterrents chemicals (Glendinning, J. I. and Hills, T. T., 1997; Glendinning, J. I. *et al.*, 1998). A Drosophila *Gr66a* taste receptor responsible for aversive response to caffeine (Moon, S. J. *et al.*, 2006), a compound that tastes bitter to humans, is unrelated to vertebrate T2R genes. This suggests that receptors for detection of aversive taste evolved independently in vertebrate and invertebrate species.

Fish and chickens have a small number of the T2R genes (ten or less; Table 1) and no pseudogenes. Mammals and frogs have much larger numbers of the T2R genes (21–64) and a high proportion of T2R pseudogenes (15–44%). An analysis of relatedness of the T2R genes in different species suggests a complex evolution of this gene family. The common ancestor of tetrapods and teleost fish already had multiple T2Rs. This initial expansion in the common ancestor of tetrapods was followed by additional independent expansions in frogs and mammals and contraction in birds (Go, Y., 2006; Shi, P. and Zhang, J., 2006).

These evolutionary changes likely reflect adaptation to different diets. It appears that the number of functional T2R genes in mammals correlates with levels of toxic compounds in different types of food. Toxic bitter compounds are more common in plant than in animal tissues (Glendinning, J. I., 1994). Correspondingly, omnivores (potentially exposed to the largest number of toxic compounds) have the

Table 1 Numbers of T1R and T2R genes in vertebrate

Species	*T1R genes*			*T2R genes*	
	T1R1 genes	*T1R2 genes*	*T1R3 genes*	*Functional and putatively functional genes*	*Pseudogenes*
Human (*Homo sapiens*)	1	1	1	28	16
Mouse (*Mus musculus*)	1	1	1	36	7
Rat (*Rattus norvegicus*)	1	1	1	37	7
Cow (*Bos taurus*)	Unknown	Unknown	Unknown	19	15
Dog (*Canis familiaris*)	1	1	1	16	5
Cat (*Felis catus*)[a]	1	0	1	Unknown	Unknown
Opossum (*Monodelphis domestica*)	1	1	1	29	5
Chicken (*Gallus gallus*)	1	0	1	3	0
Frog (*Xenopus tropicals*)	0	0	0	52	12
Fugu fish (*Takifugu rubripes*)	1	2	1	4	0
Puffer fish (*Tetraodon nigroviridis*)	1	3	1	6	0
Zebra fish (*Danio rerio*)	1	2	1	10	0

[a]Cat *Tas1r2* and *Tas1r3* data from Li X. *et al*. (2005); cat Tas1r1 is based on a cat genome sequence (GenBank accession AANG01000989) with a corresponding predicted protein 90% identical to dog T1R1.
Data from Li X. *et al.* (2005), Shi P. and Zhang J. (2006), Liao J. and Schultz P.G. (2003), Shi P. *et al.* (2003), Go Y. *et al.* (2005), Li X. *et al.* (2002a; 2002b; 2002c), Hoon M. A. *et al.* (1999), Bachmanov A. A. *et al.* (2001), Lagerstrom M. C. *et al.* (2006), Adler E. *et al.* (2000), Ishimaru Y. *et al.* (2005), Go Y. (2006), Conte C. *et al.* (2002; 2003a; 2003b), Wang X. *et al.* (2004), Wu S. U. *et al.* (2005), Bjarnadottir T. K. *et al.* (2005; 2006), Fischer R. A. *et al.* (2005), and Parry C. M. *et al.* (2004). When different sources indicated different numbers of genes, the highest estimate is shown.

largest number of T2R genes, carnivores (potentially exposed to the smallest number of toxic compounds) seem to have the smallest number of T2R genes, and herbivores are intermediate (Shi, P. and Zhang, J., 2006) (see also Table 1).

The repertoire of the T2R genes is highly conserved between the mouse and rat (Wu, S. V. *et al*., 2005) and among primate species, including humans (Fischer, A. *et al*., 2005; Go, Y. *et al*., 2005; Parry, C. M. *et al*., 2004). Primates have a smaller number of intact T2R genes and a higher number and proportion of pseudogenes compared with rodents (Conte, C. *et al*., 2003a; Go, Y. *et al*., 2005) (Table 1). Comparison of T2R sequences in rodents and primates showed that several major groups of these genes were present prior to divergence of their lineages (Conte, C. *et al*., 2003a). Consistent with this, mouse and human T2R genes reside in chromosomal regions with conserved synteny, indicating that major duplication events occurred prior to the separation of primates and rodents (Bufe, B. *et al*., 2002). Approximately 1/4 of the T2R genes have 1:1 mouse–human orthology, nearly 1/4 showed expansion in humans, and ~1/2 showed expansion in mice (Shi, P. *et al*., 2003; Bjarnadottir, T. K. *et al*., 2005). T2R gene families in rodents and primates appear to have undergone a complex combination of local and interchromosomal duplications, deletions, pseudogenization, and positive selection driving divergence of paralogous T2Rs (Conte, C. *et al*., 2003b; Shi, P. *et al*., 2003; Liman, E. R., 2006; Shi, P. and Zhang, J., 2006). The role of tandem gene duplication in evolution of the T2R genes is supported by clustering of these genes in a few chromosomal regions (Fredriksson, R. *et al*., 2003; Shi, P. *et al*., 2003).

Current literature provides conflicting views on evolution of the T2R genes in primates. Several studies suggested reduced selective constraint and neutral evolution of T2R genes in primates compared with rodents (Wang, X. *et al*., 2004; Fischer, A. *et al*., 2005; Go, Y. *et al*., 2005). These conclusions were based on analyses of rates of synonymous and nonsynonymous nucleotide substitutions, higher number of pseudogenes in primates compared with rodents, and allelic segregation of pseudogenes in humans (Conte, C. *et al*., 2003b; Kim, U. K. *et al*., 2004; Wang, X. *et al*., 2004; Fischer, A. *et al*., 2005; Go, Y. *et al*., 2005; Meyerhof, W., 2005). On the other hand, several other studies have detected signs of natural selection of the T2R genes in humans, as is likely the case with other species (Shi, P. *et al*., 2003; Wooding, S. *et al*., 2004; Soranzo, N. *et al*., 2005; Shi, P. and Zhang, J., 2006). For example, signs of positive selection were found for human *TAS2R16* gene, which encodes a receptor for β-glucopyranosides. Its ancestral allele

associated with lower sensitivity to β-glucopyranosides is under positive selection only in central Africa, while in the rest of the world the evolutionarily derived allele associated with an increased sensitivity to β-glucopyranosides is under positive selection. It was suggested that that the global pattern of allelic variation of the *TAS2R16* gene depends on selective pressures of protection against malaria in Africa and protection against toxins in malaria-free zones (Soranzo, N. *et al.*, 2005). Taster and nontaster alleles of the *TAS2R38* gene encoding a PTC taste receptor are maintained in different human populations under balancing selection. It was hypothesized that the *TAS2R38* nontaster allele encodes a functional receptor responsive to toxic bitter substances other than PTC, so that *TAS2R38* heterozygotes gain a fitness advantage because of their ability to perceive and avoid a larger number of bitter toxins compared with homozygotes (Wooding, S. *et al.*, 2004).

Evidence for both neutral evolution and natural selection of T2R genes in primates may reflect adaptation to their feeding ecology. If primates are exposed to a smaller number of toxins than their ancestors were, this may result in loss of selective pressure for some *TAS2R* genes. However, receptors involved in detection of toxins to which primates are still exposed would remain under stabilizing, balancing, or positive selection.

4.19.4 Sweet and Umami Taste

Sweetness is evoked by a diversity of chemicals, including simple carbohydrates, and in most species the sweet taste is associated with appetitive consummatory behavior (Bachmanov, A. A., 2008). Umami is a unique taste quality, described by humans as meaty or brothy, evoked by the amino acid glutamate (e.g., monosodium glutamate or MSG) and some other L-type amino acids and purine 5′-nucleotides (Lindemann, B., 2000) These two distinct taste qualities are linked because their function depends on shared GPCR proteins from the T1R family. In the mouse, three T1R-encoding genes, *Tas1r1*, *Tas1r2*, and *Tas1r3*, are located on chromosome 4 (Hoon, M. A. *et al.*, 1999; Kitagawa, M. *et al.*, 2001; Max, M. *et al.*, 2001; Montmayeur, J. P. *et al.*, 2001; Nelson, G. *et al.*, 2001; Sainz, E. *et al.*, 2001; Reed, D. R. *et al.*, 2004). The three corresponding receptor proteins, T1R1, T1R2, and T1R3, comprise a small family of class C GPCRs. This class includes also the metabotropic glutamate and extracellular calcium-sensing receptors, all of which have a large N-terminal extracellular domain. When T1R3 is coexpressed in a heterologous system with T1R2, it functions as a broad-spectrum sweet taste receptor (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002b; Nelson, G. *et al.*, 2002). In contrast, a heterodimer of T1R1 and T1R3 proteins functions as an umami taste receptor in humans, and is more broadly tuned in rodents to respond to L-amino acids (Li, X. *et al.*, 2002c; Nelson, G. *et al.*, 2002; Damak, S. *et al.*, 2003; Zhao, G. Q. *et al.*, 2003).

4.19.4.1 Strain Differences in Responses to Sweet-Tasting Stimuli

Taste sensitivity to compounds classified as tasting sweet, such as sugars, certain amino acids, and artificial sweeteners, varies among human individuals and there is evidence this may be determined genetically (e.g., Greene, L. S. *et al.*, 1975; Gent, J. F. and Bartoshuk, L. M, 1983; Reed, D. R. *et al.*, 1997). Genetic variation in sweet taste responsiveness exists also among inbred mouse strains. In early studies, C57BL mice displayed a significantly greater avidity for sucrose than did DBA/2 mice (McClearn, G. E. and Rodgers, D., 1959; 1962). Fuller J. L. (1974) noted that DBA/2 mice were indifferent to certain concentrations of sodium saccharin in two-bottle tests, whereas B6 mice strongly preferred it. Segregation ratios in a cross of these strains were reported to be consistent with a single locus, two-allele model. An autosomal gene (*Sac*) was proposed to explain this variation, with a dominant Sac^b allele in the B6 strain and a recessive Sac^d allele in the DBA/2 strain. Fuller proposed that this genetic variation affected a hedonic-based response rather than sensory threshold. Subsequent studies by Lush I. E. (1989) suggested that the *Sac* locus also influenced preference to other synthetic sweeteners, including acesulfame and dulcin. Consistent with this, earlier reports had noted that saccharin and sucrose intakes correlated among inbred strains (Pelz, W. E. *et al.*, 1973; Ramirez, I. and Fuller, J. L., 1976). Thus, early studies were supportive of a common genetic basis and single taste receptor underlying sweet taste in mice.

A detailed analysis of sweet taste behavior has been conducted with mice from the B6 and 129 strains. Compared with 129 mice, B6 mice display a higher preference for a large number of sweeteners, including sugars (sucrose and maltose) sweet-tasting amino acids (glycine, D-phenylalanine, D-tryptophan, L-proline, and L-glutamine), and several but not all noncaloric sweeteners (saccharin, acesulfame, dulcin, sucralose, and SC-45647) (Lush, I. E., 1989; Belknap, J. K. *et al.*, 1993; Capeless, C. G. and Whitney, G., 1995; Lush, I. E.

et al., 1995; Bachmanov, A. A. *et al.*, 2001d). This phenotypic difference is not due to a generalized difference in taste responsiveness or differences in appetite, but is rather specific to variation in sweet taste responsiveness (Bachmanov, A. A. *et al.*, 1996b; 2001c). Differences between these strains in preference for a sweet-tasting amino acid, glycine (Bachmanov, A. A. *et al.*, 2001d) appeared to depend on mechanisms distinct from those affecting responses to many other sweeteners. Both B6 and 129 mice generalized CTA between glycine and several other sweeteners, demonstrating that they perceive the sucrose-like taste of glycine. Thus, the lack of a strong glycine preference by 129 mice cannot be explained by their inability to perceive its sweetness (Manita, S. *et al.*, 2006). Despite differences in glycine intakes and preferences, chorda tympani (CT) responses to glycine are similar in mice from both strains (Inoue, M. *et al.*, 2001b). Neither behavioral nor neural responses to glycine are influenced by the *Tas1r3* genotype (Eylam, S. and Spector, A. C., 2004; Inoue, M. *et al.*, 2004b), suggesting that variation in taste responses to glycine depends on other genes.

4.19.4.2 Mapping and Identification of Sweet Taste Receptor Genes

Linkage studies conducted with BXD RI strains, or in crosses with B6 and DBA/2 or 129 strains, detected at least one to two loci on mouse chromosome 4 influencing sweetener preferences (Lush, I. E., 1989; Belknap, J. K. *et al.*, 1992; Phillips, T. J. *et al.*, 1994; Lush, I. E. *et al.*, 1995; Blizard, D. A. *et al.*, 1999). Bachmanov A. A. *et al.* (1997) reported the existence of two distinct loci on chromosome 4 (including *Sac*) in a B6 by 129 cross that collectively accounted for more than 50% of the genetic variability in sucrose intake; these loci were also shown to affect the magnitude and threshold of the CT response to sucrose. A subsequent positional cloning study demonstrated that the *Sac* locus in the subtelomeric region of chromosome 4 corresponded to the *Tas1r3* taste receptor gene (Figure 5) (Bachmanov, A. A. *et al.*, 2001b; Li, X. *et al.*, 2002a).

Polymorphisms of *Tas1r3* have been linked to sweet taste responses attributed to allelic variants of the *Sac* locus (Figure 5). A comprehensive quantitative analysis of *Tas1r3* sequence variants associated with saccharin preference using 30 inbred mouse strains yielded association at a haplotype including the amino acid substitution of isoleucine to threonine at position 60 (Ile60Thr) (Reed, D. R. *et al.*, 2004). A subsequent *in vitro* study showed that a corresponding site-directed mutation changes binding affinity of the T1R3 protein to several sweeteners (Nie, Y. *et al.*, 2005).

The T1R2 + T1R3 sweet receptor responds to a broad variety of ligands in both humans and rodents (although there are species differences), including sugars, artificial sweeteners, and sweet-tasting amino acids (Nelson, G. *et al.*, 2001; Li, X. *et al.*, 2002b; Nelson, G. *et al.*, 2002). There is also evidence that T1R3 functions as a low-affinity sugar receptor alone, probably as a homodimer (Zhao, G. Q. *et al.*, 2003).

Aside from the *Tas1r* family, there may be other genes that affect sweet taste. Multigenic inheritance of sweetener preferences was shown in a number of studies (Ramirez, I. and Fuller, J. L., 1976; Phillips, T. J. *et al.*, 1994; Capeless, C. G. and Whitney, G., 1995; Lush, I. E. *et al.*, 1995; Bachmanov, A. A. *et al.*, 1996a). Mice lacking T1R3 have detection thresholds for sucrose identical to wild types, and can discriminate among sweet and savory stimuli (Delay, E. R. *et al.*, 2006). In F_2 hybrids produced from B6 and 129 strains, intake and neural response of the sweet amino acid glycine was not linked to *Tas1r3* (Inoue, M. *et al.*, 2004b), suggesting the possibility of a non-T1R mechanism. One of the genetic loci affecting sweet taste responses is *dpa* (D-phenylalanine aversion), which affects ability of mice to generalize CTA between D-phenylalanine and sucrose, inferring that *dpa* affects ability to detect sweetness of D-phenylalanine. The *dpa* locus also affects responses of sweet-sensitive fibers of the CT nerve to D-phenylalanine. B6 mice carry a dominant allele of *dpa* that determines an ability to recognize the sweetness of D-phenylalanine, whereas BALB/c mice carry a recessive *dpa* allele conferring inability to detect D-phenylalanine sweetness. The *dpa* locus was mapped to proximal chromosome 4, a region distinct from the subtelomeric chromosome 4 harboring the *Tas1r* genes (Ninomiya, Y. *et al.*, 1987; 1991; 1992; Shigemura, N. *et al.*, 2005). A locus on proximal chromosome 4, in the *dpa* region, was found to be suggestively linked to consumption of, and CT responses to, sucrose (Bachmanov, A. A. *et al.*, 1997). An epistatic interaction between effects on sucrose intake of this locus and the *Tas1r3* locus suggests that these two loci may encode interacting components of sweet taste transduction (Bachmanov, A. A. *et al.*, 1997).

4.19.4.3 Umami Taste Genetics

Little is known about genetic variation in umami taste responses. Humans appear to differ in perception of glutamate taste (Lugaz, O. *et al.*, 2002), but it is not

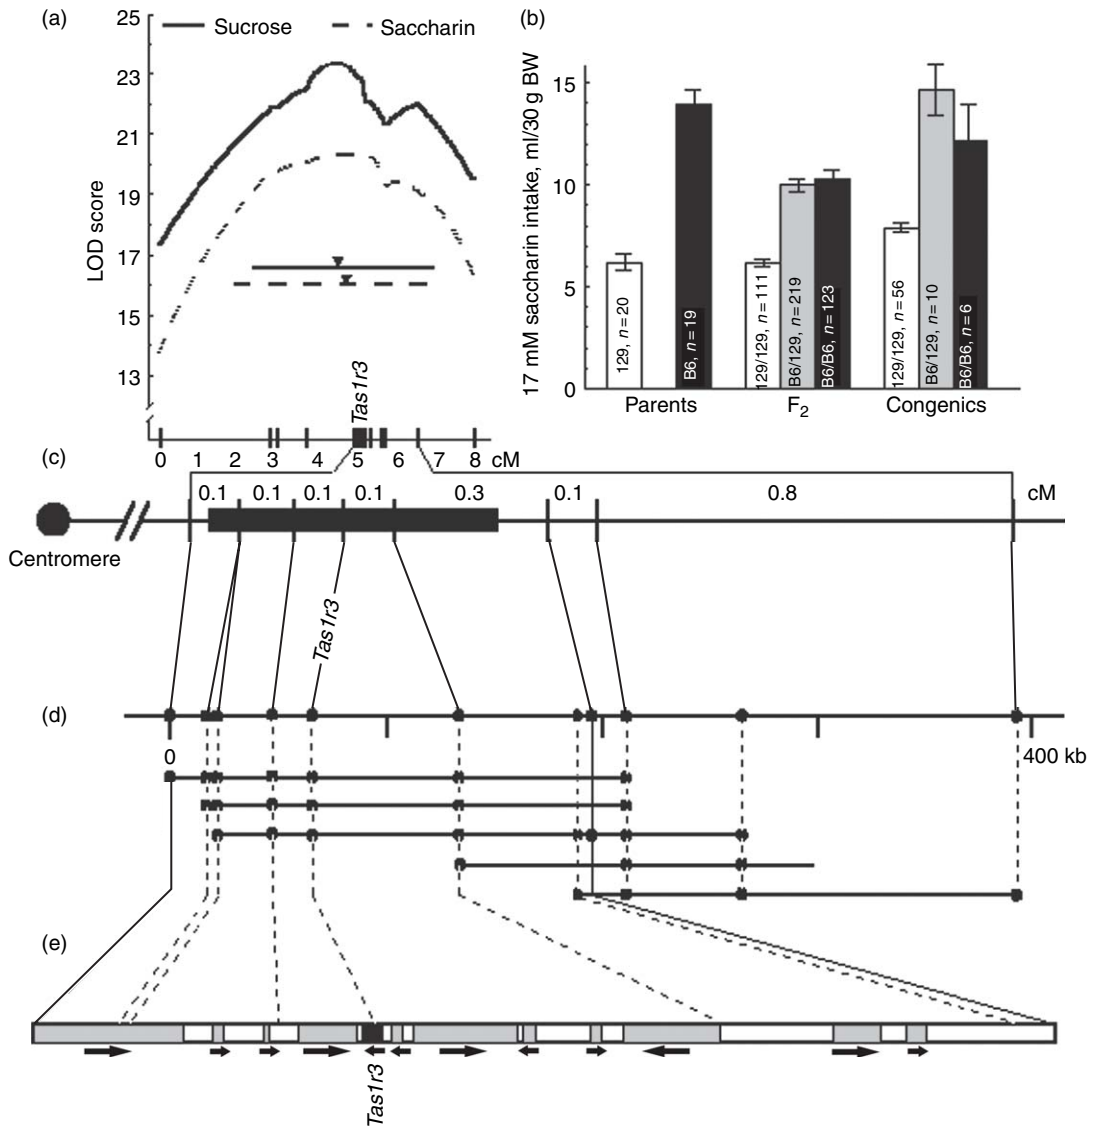

Figure 5 Positional identification of the *Sac* (saccharin preference) locus. (a) Linkage map of mouse distal chromosome 4 based on data from the B6 × 129 F_2 intercross. The *X*-axis shows distances between markers in recombination units (cM). The *Y*-axis shows the logarithm of the odds ratio (LOD) scores for sucrose and saccharin consumption. The LOD score peaks (indicated by black triangles) and confidence intervals (solid horizontal line for sucrose, 4.5 cM, and dotted horizontal line for saccharin, 5.3 cM) define the genomic region of the *Sac* locus. (b) Average daily 17 mM saccharin consumption by mice from parental 129 and B6 strains (left), B6 × 129 F_2 hybrids (center), and congenic 129.B6-*Sac* mice (right) in 96 h two-bottle tests with water (means ± SE). *Tas1r3* genotypes of the F_2 and congenic mice and mouse numbers are indicated on the bars. Differences between parental strains and among the F_2 and congenic genotypes were significant ($p < 0.0001$, ANOVA). F_2 and congenic B6 homozygotes and heterozygotes for *Tas1r3* did not differ from each other, and had higher saccharin intakes compared with 129 homozygotes ($p < 0.0001$, posthoc tests). (c) Linkage map of the *Sac*-containing region defined based on the size of the donor fragment in the 129.B6-*Sac* congenic strain (black box). Distances between markers were estimated based on the B6 × 129 F_2 intercross (see panel a). (d) A contig of bacterial artificial chromosome (BAC) clones and physical map of the *Sac* region. BAC clones are represented by horizontal lines. Dots indicate marker content of the BAC clones. (e) Genes within the *Sac*-containing interval. Filled areas indicate predicted genes. Arrows indicate the predicted direction of transcription. Reproduced from Bachmanov, A. A., Reed, D. R., Li, X., and Beauchamp, G. K. 2002. Genetics of sweet taste preferences. Pure Appl. Chem. 74, 1135–1140, with permission from IUPAC.

known whether this variation has a genetic basis. Genetically determined differences in responses to umami taste stimuli were shown in mice: in two-bottle tests, B6 mice display higher consumption of MSG and inosine monophosphate than do mice from the 129 strain (Bachmanov, A. A. *et al.*, 2000). These strain differences seem to be specific for umami stimuli and are not associated with variation in sweet or salty tastes (Bachmanov, A. A. *et al.*, 1996a; 1998; 2000).

A heterodimer of the T1R1 and T1R3 proteins is thought to function as a receptor for umami taste stimuli. Consistent with this, disruption of the *Tas1r1* and/or *Tas1r3* genes diminishes behavioral or neural responses of knockout mice to umami taste stimuli (Nelson, G. *et al.*, 2002; Damak, S. *et al.*, 2003; Zhao, G. Q. *et al.*, 2003). However, natural allelic variation of the *Tas1r3* gene does not affect umami taste responses in mice: an analysis of the F_2 hybrids between the B6 and 129 inbred mouse strains has shown that the *Tas1r3* allelic variants are not associated with behavioral or neural taste responses to umami stimuli (Inoue, M. *et al.*, 2004b). Therefore, although the T1R3 receptor is involved in transduction of umami taste, the B6/129 sequence variants affecting its sensitivity to sweeteners do not affect its sensitivity to umami compounds. Recent studies of umami taste transduction indicate the existence of more than one receptor responding to this class of stimuli (Chaudhari, N. *et al.*, 2000; Maruyama, Y. *et al.*, 2006); allelic variation of these genes might underlie genetic differences in umami taste.

4.19.4.4 Evolution of T1R Receptors

Numbers of the T1R genes in different vertebrate species range from complete absence in the frog to five in the puffer fish and medaka fish (Table 1). With the exception of the frog, all vertebrates have single T1R1 and T1R3 genes, but the number of the T1R2 genes varies: the chicken and Felidae species (domestic cat, tiger, and cheetah; Li, X. *et al.*, 2005) lack functional T1R2 genes, but several fish species have two to three T1R2 genes. The vertebrate T1R receptors are not found in invertebrates (Bjarnadottir, T. K. *et al.*, 2005) and are not related to a Drosophila taste receptor for a sugar trehalose encoded by the *Gr5a* gene (Dahanukar, A. *et al.*, 2001; Ueno, K. *et al.*, 2001; Chyb, S. *et al.*, 2003; Inomata, N. *et al.*, 2004; Isono, K. *et al.*, 2005; Hallem, E. A. *et al.*, 2006).

These data allow us to establish changes in the T1R repertoire during evolution. Although many vertebrate and invertebrate animals detect the taste of sugars and avidly consume them, receptors for sugars evolved independently in these two lineages. Most vertebrates have three clades of T1R genes, suggesting that all three evolved before separation of tetrapods and teleosts (Shi, P. and Zhang, J., 2006). However, another group concluded from a similar analysis that fish and mammalian T1R1 and T1R3 genes are orthologs, but fish and mammalian T1R2 evolved independently (Ishimaru, Y. *et al.*, 2005). It appears that after separation of tetrapods and teleosts, duplication of the T1R2 gene occurred in the evolution of different fish species. Several Felidae species (Li, X. *et al.*, 2005) and the chicken (Lagerstrom, M. C. *et al.*, 2006; Shi, P. and Zhang, J., 2006) lost the T1R2 gene, and the tongueless western clawed frog lost all three T1R genes. Thus, pseudogenization of the T1R2 gene occurred multiple times in evolution.

Loss of the T1R2 gene in cats and chickens must result in the absence of the T1R2 + T1R3 sweet taste receptor, which corresponds to the lack of taste responses to sweeteners in these species (Kare, M. R., 1961; Halpern, B. P., 1962; Bartoshuk, L. M *et al.*, 1975; Beauchamp, G. K. *et al.*, 1977; Ganchrow, J. R. *et al.*, 1990). Interestingly, some birds recognize sugar taste (Matson, K. D. *et al.*, 2000; 2001), suggesting that they may have a functional T1R2. The T1R2 pseudogenization and lack of sweet taste responsiveness in cats are probably results of these animals being obligate carnivores that do not seek sugars in their food, and thus do not have a selective advantage of having a functional sweet taste receptor that recognizes sugars. Dogs, which are carnivores from the Canidae family, have a functional T1R2 gene structure (Li, X. *et al.*, 2005; Shi, P. and Zhang, J., 2006) and are attracted to sugars (Grace, J. and Russek, M., 1969). Thus, loss of the T1R2 gene in cats and chickens may be a consequence of their feeding behavior that does not require a sweet taste receptor for proper food choice. However, a reverse causative relationship cannot be excluded, when a loss-of-function mutation in the T1R2 gene resulted in loss of sweet taste sensation, which in turn altered feeding behavior of these animals.

The role of natural selection in evolution of the T1R genes was shown in several studies involving comparisons of the paralogous genes and analyses of their within-species variation. Sequence divergence among the paralogous T1R genes appears to be governed by positive selection (Shi, P. and Zhang, J., 2006). Most of the inferred positively selected sites are located in the N-terminal extracellular domains of the T1R proteins (Shi, P. and Zhang, J., 2006),

which participate in ligand binding (Xu, H. *et al.*, 2004; Jiang, P. *et al.*, 2005a, Nie, Y. *et al.*, 2005). Analysis of within-species *TAS1R* sequence variation among humans suggested that *TAS1R* variants have come to their current frequencies under positive natural selection during population growth, which implies that the coding sequence variants affect receptor function (Kim, U. K. *et al.*, 2006).

Results of these studies suggest that the evolutionary changes of the T1R receptors are likely to affect their ligand binding properties. This is consistent with currently available data on species differences in ligand specificity of the T1R1 + T1R3 and T1R2 + T1R3 receptors (Nelson, G. *et al.*, 2001; 2002; Li, X. *et al.*, 2002c; Winnig, G. *et al.*, 2005). Several studies have shown that sequence variation between the T1R orthologs underlies species differences in responses to several amino acids, sweeteners and sweet taste blockers. T1R variants that determine species differences in ligand binding were found in the cysteine-rich region of the extracellular N-terminal domain (Jiang, P. *et al.*, 2004) and in the transmembrane domains (Jiang, P. *et al.*, 2005a; 2005b; Winnig, G. *et al.*, 2005).

Although ligands for the T1R receptors have been experimentally confirmed only for humans and rodents, it is likely that their orthologs in other species have similar ligand specificities. This would make sense because sugars and amino acids, the main natural T1R ligands, are important nutrients for animals of many different species. This explains the lower diversity and slower evolution of the T1R genes compared with the T2R genes involved in bitter taste (Shi, P. and Zhang, J., 2006). Nevertheless, variation in the T1R genes among species may reflect species differences in diets, for example the amino acid composition of food or presence of sweet proteins in some tropical fruits.

4.19.5 Salt and Sour Taste

Ionic taste stimuli such as H^+ or Na^+ are thought to be transduced primarily via apically located ion channels. A large portion of NaCl or salt taste is thought to be dependent on the influx of sodium through epithelial sodium channels, members of the degenerin/ENaC superfamily of ion channels. ENaC is blocked by the diuretic compound amiloride. Taste receptor cells (TRCs) express Na^+-selective channels that are also blocked by amiloride and share a number of other physiological properties with the ENaCs (for a review, see Boughter, J. D., Jr. and Gilbertson, T. A., 1999; Gilbertson, T. A. *et al.*, 2000). Entry of the sodium ion through these channels depolarizes the taste cell. However, the specific identity of these channels, as well as the mechanisms by which salty taste of non-sodium salts is transduced, are not well understood (Chandrashekar, J. *et al.*, 2006). Sour-tasting (acid) stimuli also depolarize TRCs either by activating cation channels, or by direct permeation of protons through ion channels, including ENaC (Gilbertson, T. A. *et al.*, 1992; Gilbertson, T. A. and Boughter, J. D., Jr., 2003). Additionally, transient receptor potential (TRP) channels have been shown to be involved in acid taste (Huang, A. L. *et al.*, 2006; Ishimaru, Y. *et al.*, 2006).

Comparatively few studies have reported genetic variation affecting taste responses to salty or sour substances. Inbred strain differences have been reported for NaCl preferences in both mice (Hoshishima, K. *et al.*, 1962; Ninomiya, Y. *et al.*, 1989; Beauchamp, G. K., 1990; Lush, I. E., 1991; Bachmanov, A. A. *et al.*, 2002; Tordoff, M. G. *et al.*, 2007) and rats (Midkiff, E. E. *et al.*, 1985). Among commonly used strains, B6 and BALB are NaCl avoiding, and their CT response to NaCl is amiloride sensitive, whereas DBA/2, C3H/He, and 129 mice are NaCl-tolerant and their CT response to NaCl is amiloride-insensitive (Ninomiya, Y. *et al.*, 1989; Gannon, K. and Contreras, R. J., 1993; Ninomiya, Y., 1996). Experiments using isolated taste buds indicated that the strain difference might be due to a difference in the density of functional amiloride-sensitive Na^+ channels on taste cells (Miyamoto, T. *et al.*, 1999). Although B6 and DBA/2 mice differ in terms of the amiloride sensitivity of their CT response to NaCl (Ninomiya, Y. *et al.*, 1989), these strains do not differ in detection or discrimination of salts, and these behaviors are attenuated by amiloride in a similar fashion in both strains (Eylam, S. and Spector, A. C., 2003; 2005). More studies are needed to determine whether there is a relationship between amiloride sensitivity of neural responses to NaCl, and NaCl preference. The genetic variation in voluntary NaCl consumption may also depend on a variety of other factors in addition to peripheral taste responsiveness.

4.19.6 Taste and Other Complex Phenotypes

4.19.6.1 Taste and Diet

Taste sensitivity is associated with food choice and intake, and taste preferences are a predictor of propensity to consume sweet or high-fat foods (e.g., Bartoshuk, L., 1980; Drewnowski, A. *et al.*, 1985; Anliker, J. A. *et al.*, 1991; Drewnowski, A. J. *et al.*, 1998; Salbe, A. D. *et al.*,

2004). At least some of this association is underlied by allelic variation of taste receptor genes (Mennella, J. A. *et al*., 2005; Dinehart, M. E. *et al*., 2006; Reed, D. R. and McDaniel, A. H., 2006; Sandell, M. A. and Breslin, P. A., 2006). Unexpectedly, haplotypes at the *TAS2R38* gene encoding the PTC receptor were significantly related to children's to preference for sucrose and sweet-tasting foods and beverages: Those possessing taster alleles tended to be sweet preferrers; the authors speculate that the PTC gene may be in linkage disequilibrium with sweet taste genes (Mennella, J. A. *et al*., 2005). Other studies have shown that *TAS2R38* genotype or PROP taster status affects perception of bitterness of vegetables, such as broccoli, turnips, or Brussels sprouts, and hence may influence dietary selection (Dinehart, M. E. *et al*., 2006; Sandell, M. A. and Breslin, P. A., 2006). It is furthermore possible that there is a relationship between genetic determinates of taste sensitivity and obesity (Bartoshuk, L. M *et al*., 2006).

There is a strong relationship between taste and feeding (Scott, T. R., 2001), and future taste-related gene discovery may focus on the interaction of taste processing with homeostatic systems involved in the regulation of feeding, appetite, fluid balance, reward, and drug administration.

4.19.6.2 Taste and Drug Intake

It has long been appreciated that a consistent predictor of alcohol (ethanol) drinking in rodents is avidity for consumption of sweet-tasting compounds. Positive correlations between ethanol and sweetener intake have been noted in multiple strains of rats and mice, and a common genetic basis is strongly supported by a robust association of these phenotypes in both selected lines and segregating populations (McClearn, G. E. and Rodgers, D., 1959; Belknap, J. K. *et al*., 1993; Overstreet, D. H. *et al*., 1993; Bachmanov, A. A. *et al*., 1996b; Dess, N. K. *et al*., 1998; Stewart, R. B. *et al*., 2003). There is also substantial evidence for an association between alcohol drinking and sweet taste in humans (Yamamoto, M. E. *et al*., 1991; Kampov-Polevoy, A. *et al*., 1997; 2003; 2004). *Tas1r3* knockout mice do not prefer ethanol unlike their wild-type controls, strongly arguing for a direct role of the sweet taste receptor in mediating ethanol intake (Blednov, Y. A. *et al*., 2007). In rats, ethanol applied to the tongue selectively activates a subpopulation of sweet-responsive taste neurons in the CNS, and this activity is blocked by lingual application of gurmarin, a peripheral antagonist of sweet taste (Lemon, C. H. *et al*., 2004).

There is also an association of bitter taste sensitivity with alcohol, caffeine and nicotine use (Hall, M. J. *et al*., 1975; Mela, D. J., 1989; Mela, D. J. *et al*., 1992; Mattes, R. D., 1994; Enoch, M. A. *et al*., 2001; Snedecor, S. M. *et al*., 2006). This association may be due to individual variation in bitter taste receptors. For example, subjects possessing nontaster haplotypes at the *TAS2R38* locus rate alcoholic beverages as less bitter, and more preferred (Duffy, V. B. *et al*., 2004; Lanier, S. A. *et al*., 2005). Similarly, there is a greater percentage of bitter-insensitive individuals among smokers than nonsmokers, suggesting these nontasters may be at risk for nicotine addiction (Enoch, M. A. *et al*., 2001). Because there is a strong relationship between smoking and alcohol use in humans (Pomerleau, C. S. *et al*., 2004) it is reasonable to assume taste may be a common factor in both addictions. However, oral somatosensory factors may also play a role because both nicotine and ethanol are trigeminal irritants (e.g., Carstens, E. *et al*., 1998). In addition, causative relationships between taste and drug intake may be more complex, as drug intake may influence taste sensitivity. There is evidence that long-term smoking or oral tobacco use may contribute to a decrement in overall taste acuity (Sato, K. *et al*., 2002; Khan, G. J. *et al*., 2003), and taste detection thresholds for caffeine are elevated in habitual caffeine drinkers relative to nonusers (Mela, D. J. *et al*., 1992).

4.19.7 Conclusions

Historically, behavioral genetic studies of taste and intake behaviors have been instrumental in the eventual discovery of G-protein-coupled taste receptors. In particular, the discovery of the PTC polymorphism in humans stimulated research into the genetics basis of taste behavior. In rodents, strain differences in responsiveness to bitter- and sweet-tasting stimuli, primarily in two-bottle tests, provided linkages to chromosome regions later found to harbor taste receptor genes. However, the balance of evidence suggests that taste-related behaviors are under polygenic control, and other genes have yet to be elucidated. Within- and between-species differences in the T1R and T2R genes are associated with variation in taste-related behaviors. The evolution of the T1R and T2R gene families reflects adaptation strategies of different species to their chemical environments and feeding ecology.

Glossary

category scale A method of rating perceived intensity in which subjects place ratings in categories (e.g., a 9-point scale, in which 1 = very weak, 5 = medium, and 9 = very strong).

chorda tympani A branch of the facial nerve (cranial nerve VII) that carries taste information from the mobile, anterior two-thirds of the tongue.

flavor The combined sensations of taste, oral somatosensation, and retronasal olfaction.

gLMS General labeled magnitude scale, a method of rating perceived intensity. The scale is a numbered line running from 0 = no sensation to 100 = strongest imaginable sensation of any kind with intermediate labels: 1.4 = barely detectable, 6 = weak, 16 = moderate, 35 = strong, and 53 = very strong. This spacing of labels gives the scale ratio properties, that is, a rating of 40 denotes a perceived intensity twice as strong as a rating of 20.

magnitude matching A method of rating-perceived intensity that permits valid comparisons across groups. This technique depends on the ability of subjects to match the intensities of different types of sensations. Subjects rate the perceived intensities of stimuli of interest relative to an unrelated standard. By assuming that variability in the intensity of the standard is equivalent across two or more groups, magnitude matching permits group comparisons of the stimulus of interest.

orthonasal olfaction Odor sensations arising from environmental stimuli that are sniffed.

PROP 6-*n*-Propylthiouracil, a compound that binds to the T2R38 receptor and to which some individuals are taste blind.

PTC Phenylthiocarbamide, a compound that binds to the T2R38 receptor and to which some individuals are taste blind.

retronasal olfaction Odor sensations arising from foods in the mouth; these are pumped into the nasal cavity via the rear of the throat during chewing and swallowing.

supertaster An individual who experiences the most intense oral sensations (i.e., taste, oral burn, oral touch) and the most intense retronasal olfactory sensations.
tastant A substance that evokes a taste sensation.
VAS Visual analog scale, a method of rating-perceived intensity in which subjects mark a line labeled with the minimum and maximum intensities possible for a given sensory experience.

4.20.1 Discovery of Taste Blindness

Taste blindness was discovered by accident in 1931. Arthur Fox, a chemist working for DuPont de Nemours, synthesized some phenylthiocarbamide (PTC), and when he attempted to put the compound into a bottle, some of it escaped. One of his colleagues, Dr. C. R. Noller, an eminent organic chemist, noticed a bitter taste; Fox did not. Testing co-workers (Fox, A. L., 1931) revealed that the majority tasted PTC as bitter. When Fox and a prominent geneticist of the day asked 2550 attendees at a meeting of the American Association for the Advancement of Science to vote on the quality of taste from PTC crystals (Blakeslee, A. F. and Fox, A. L., 1932), they confirmed that most tasted bitter (tasters) but a substantial number (28%) did not (nontasters). When *The Journal of Heredity* published these data, the editor had small pieces of filter paper impregnated with PTC inserted into the journal. Readers could purchase these PTC papers which facilitated testing of a variety of groups (e.g., the Dionne quintuplets were all tasters; Ford, N. and Mason, A. D., 1941). Family studies (Snyder, L. H., 1931) suggested that nontasting was recessive.

The informal testing of that era was displaced by more quantitative threshold methodology (Harris, H. and Kalmus, H., 1949) that produced the now-familiar bimodal distribution of PTC thresholds. Evaluation of a series of compounds showed that those containing the N–C═S group (including PTC and 6-*n*-propylthiouracil (PROP)) produced the bimodal distribution. Studies in this early era focused on assessing percentages of tasters by race, sex, and various disease states.

Fischer brought new insights to taste blindness. He stopped using PTC and switched to PROP because it lacked the sulfurous odor of PTC. In addition, he added an assessment for quinine; he reasoned that PROP thresholds assessed a specific sensitivity while quinine thresholds assessed a general ability to taste (Fischer, R., 1967). He began to consider the implications of sensory variation for behavior relevant to health; he found associations between taste thresholds (PROP and quinine) and food preferences, alcohol abuse, cigarette smoking, and body weight.

Most recently, Drayna's group found that the gene for PTC/PROP tasting is located on chromosome 7 (Kim, U. K. *et al.*, 2003). Those individuals with nontaster thresholds (PROP threshold > 0.0002 M) were homozygous for the recessive allele; those with taster thresholds (PROP threshold < 0.0001 M) were either homozygous for the dominant allele or were heterozygous. The human genome project has resulted in the discovery of a variety of other taste-related genes as well (e.g., Mombaerts, P., 2004). In the future, the elucidation of ligands for the receptors expressed by those genes and the development of more accurate methods for oral sensory genotype/phenotype analysis will make possible more detailed studies of the associations between oral sensation and health.

4.20.2 New Psychophysical Methods and the Discovery of Supertasters

4.20.2.1 Visual Analog Scales and Category Scales: Invalid for Across-Group Psychophysical Comparisons

Fischer lacked the psychophysical tools we have today, but his speculations on health outcomes associated with genetic differences in taste foreshadowed the results that are now emerging. With the new tools that modern scaling studies provide, the magnitude of the associations between sensation and behavior can finally be quantified.

The search for associations between diet, smoking, alcohol intake, and the ability to taste PROP requires comparisons between the sensations

experienced by nontasters and tasters. Unfortunately, many of the studies searching for these associations used labeled scales (e.g., visual analog scale (VAS) and category scales like the Natick 9-point scale or the labeled magnitude scale (Green, B. G. *et al.*, 1993)). Comparisons across nontasters and tasters cannot be made with these scales. That is, these scales are valid for making within-subject comparisons or making comparisons across groups where the group members are randomly selected, but they are invalid for making across-group comparisons. The explanation will be briefly reviewed here but the interested reader is referred to more complete treatments of the issue (Bartoshuk, L. M. 2002; Bartoshuk, L. M. *et al.*, 2002; Bartoshuk, L. M. *et al.*, 2004a; 2005b; Snyder, D. J. *et al.*, 2004; Bartoshuk, L. M. *et al.*, 2006b).

VAS and category scales are usually anchored in terms of the minimum and maximum of the sensation to be measured. For example, a VAS used to assess sweetness was a line labeled "not at all" at one end and "extremely" at the other end (Salbe, A. D. *et al.*, 2004); similarly, a 9-point category scale for sweetness was labeled 1 = "not at all" and 9 = "extremely" (Drewnowski, A. *et al.*, 1997). Intermediate values on category scales may be labeled as well; another 9-point category scale was labeled 1 = "none," 3 = "slight," 5 = "moderate," 7 = "strong," and 9 = "extreme" (Kamen, J., 1959).

Unfortunately, the intensity labels on these scales do not denote the same perceived intensities to all. Suppose that groups of nontasters and tasters were presented with a series of sucrose solutions varying in concentration from near threshold to very concentrated and asked to select one they would describe as strong. In this situation, nontasters and tasters would select similar concentrations. However, if they were then asked to don earphones and set the loudness of a tone to match the sweetness of the sucrose they had selected, the two groups would behave differently. The nontasters would match the sweetness they experienced to a lower tone intensity than would the tasters. Since we have no reason to believe that nontasters and tasters hear differently, this result shows that nontasters experienced less sweetness than did the tasters even though both groups described the sweetness as strong (e.g., see Bartoshuk, L. M. and Snyder, D. J. 2004 or Snyder, D. J. *et al.*, 2004 for the data on which this example was based).

In other words, intensity descriptors are relative. The mental intensity ruler that we apply to sensations behaves as if it were printed on elastic; this ruler expands or contracts with the sensory domain of interest, the physiological capacity of that domain, and the individual's experience. The relativity of intensity descriptors was captured in a dramatic quote from Stevens S. S. (1958, p. 633): "Mice may be called large or small, and so may elephants, and it is quite understandable when someone says it was a large mouse that ran up the trunk of the small elephant."

Invalid comparisons have been discussed periodically throughout the history of scale development (e.g., Aitken, R. C. B. 1969; Narens, L. and Luce, R. D. 1983; Biernat, M. and Manis, M. 1994; Birnbaum, M. H. 1999). These errors most often result in the failure to see real differences, but occasionally they will produce erroneous differences that appear to go in the wrong direction (e.g., see the results for KCl taste in Schifferstein, H. N. J. and Frijters, J. E. R., 1991 and NaCl taste in Drewnowski, A. *et al.*, 1997). Most of the early failures to find differences between nontasters and tasters can be attributed to this measurement error.

4.20.2.2 Magnitude Matching

The sweetness experiment above demonstrates a serious problem with sensory measurement, but it also suggests a solution. When two groups apply the same intensity descriptor to a given sensory experience, this does not mean that the two groups are experiencing the same perceived intensity. In order to reveal differences in perceived intensities between two groups, members of those groups should be asked to compare the sensation of interest to an unrelated standard. There will be variation in the perception of the standard within each of the two groups, but if the standard is unrelated to the sensation of interest, that variation will be roughly the same for both groups. The use of an unrelated standard led to the formalization of the method of magnitude matching (Hall, M. J. *et al.*, 1975; Marks, L. E. and Stevens, J. C., 1980; Stevens, J. C. and Marks, L. E., 1980; Marks, L. E. *et al.*, 1988). Magnitude matching is feasible using any ratio method (e.g., magnitude estimation (Stevens, S. S., 1969), general labeled magnitude scale (Bartoshuk, L. M. *et al.*, 2004b), general VAS (Bartoshuk, L. M. *et al.*, 2005b)) that permits assessments of both sensations of interest and independent standards on the same scale. Recent work shows that these standards need not be actual stimuli, but may include remembered sensations (e.g., the brightest light ever seen, the loudest sound ever heard, the

strongest sensation of any kind ever experienced) (Bartoshuk, L. M. *et al.*, 2005b).

4.20.2.3 Supertasting, Oral Burn, and Oral Touch

As data collected with magnitude matching accumulated, significant differences among tasters became apparent. A subgroup of tasters were found to experience not only the greatest bitterness from PROP but also the greatest taste intensities from all other tastants as well. These supertasters also experienced the most intense burn from oral irritants (e.g., chili peppers) as well as the most intense oral tactile sensations (e.g., fats) (Duffy, V. B. *et al.*, 1996; Tepper, B. J. and Nurse, R. J. 1997; Prutkin, J. M. *et al.*, 2000; Hayes, J. E. *et al.*, 2007).

Insights from Miller's anatomical studies help to explain these associations. Miller, I. J. and Whitney G. (1989) discovered a relationship between taste intensity and taste bud density in mice, and they suggested that a similar relationship could explain human variation in taste intensity. They were correct; the density of fungiform papillae (i.e., structures that contain taste buds on the anterior tongue) shows great variability in humans. Moreover, the taste buds on fungiform papillae are surrounded by nerve fibers that mediate oral burn/pain sensations, and other areas on fungiform papillae are innervated by fibers that mediate oral touch sensations (e.g., see Bartoshuk, L. M. *et al.*, 2006a for a discussion). Thus, the more fungiform papillae an individual has, the more intense the experiences of taste, oral burn, and oral touch.

4.20.2.4 Pathology

Inhibition among brain regions mediating oral sensation also contributes to individual differences (e.g., Bartoshuk, L. M. *et al.*, 2005c). While widespread oral sensory damage compromises perceived taste intensity, damage to a localized part of this system can release inhibition in other parts, producing paradoxical increases in perceived taste intensity. Further, the presence of central interactions between the taste and trigeminal systems means that taste damage may intensify nontaste oral sensations. In short, oral sensory variation is the joint result of genetic, anatomical and pathological variation. One of the major goals of modern research into associations between sensory experience and health is to assess the degree of variance explained by each of these sources and their interactions (e.g., Dinehart, M. E. *et al.*, 2006).

Oral sensory pathology cannot be assessed without testing function at individual nerve fields in the mouth, mainly because disinhibition maintains the constancy of whole-mouth perception, thus masking local pathology. We assess regional oral sensation with a spatial test using scaling methodology that includes an unrelated standard (e.g., Dinehart, M. E. *et al.*, 2006).

4.20.2.5 How Are Supertasters Defined?

As our understanding of taste blindness has evolved, so too has our ability to assess oral sensory function accurately. The discovery of taste blindness involved a binary question: does PTC taste bitter or not (Fox, A. L., 1931)? Threshold testing (Fischer, R. and Griffin, F., 1964) subsequently led to quantitative criteria to classify subjects as nontasters or tasters of PROP, while the development of suprathreshold scaling methods subdivided tasters into supertasters and medium tasters (Bartoshuk, L. M. *et al.*, 1994). PROP supertasters proved to be supertasters in general – that is, they experience the most intense tastes from non-PROP tastants – and super-perceivers of oral burn and oral touch. Recent advances in anatomical and genetic assessment have added further complexity, but for historical and practical reasons, we believe that psychophysical criteria are the most important determinants of oral sensory function; after all, taster status should reflect how people actually experience taste.

We initially suspected that taste blindness arose from a single gene (i.e., supertasters = homozygous dominant, medium tasters = heterozygous, nontasters = recessive), but the discovery that fungiform papilla density correlates with suprathreshold PROP bitterness (Bartoshuk, L. M. *et al.*, 1994) suggested another possibility: supertasters of PROP might be tasters (homozygous or heterozygous) bearing the largest number of fungiform papillae. Fortunately, the identification of a gene (*T2R38*) encoding a PTC/PROP taste receptor (Kim, U. K. *et al.*, 2003) permitted further resolution. The most common alleles for this gene are distinguished by specific amino acid differences at crucial positions – Ala49Pro, Val262Ala, and Ile296Val – with the two most common haplotypes noted as PAV and AVI. Nontasters carry two recessive alleles (AVI/AVI), while tasters are heterozygous (PAV/AVI) or carry two dominant alleles (PAV/PAV). Genotype analysis

alone, however, is insufficient for classification, mainly because *T2R38* genotypes associate with threshold measures of PTC/PROP bitterness (Kim, U. K. *et al*., 2003), but not with suprathreshold measures. Individuals expressing PAV/PAV perceive slightly more suprathreshold PROP bitterness than do those expressing PAV/AVI, but the difference is too small to account for psychophysical measures of supertasting (Duffy, V. B. *et al*., 2004a).

Figure 1 demonstrates the utility of using only suprathreshold perceived intensity to define taster status. Threshold measures (left panel) divide subjects into the two groups identified in early studies (i.e., nontasters and tasters). But a different picture emerges when both of these groups are subdivided by suprathreshold PROP intensity (right panel). Consistent with our previous work, we separated subjects with taster thresholds (i.e., PAV/PAV or PAV/AVI) into those who perceive the least bitterness (i.e., medium tasters) and those who perceive the most (i.e., supertasters), resulting in greater group differences across a wider intensity range. When we separated subjects with nontaster thresholds (i.e., AVI/AVI) in the same fashion, we found that some of these individuals produce a suprathreshold function that classifies them as medium tasters. In other words, genetic analysis of *T2R38* fails to identify supertasters and includes among nontasters those who experience considerable bitterness from PROP.

Why is this? Recently, Hayes and Duffy (Hayes, J. E., 2007) showed that fungiform papilla density is largely independent of *T2R38* genotype. We previously reported (Bartoshuk, L. M. *et al*., 1994) that nontasters tend to have the fewest fungiform papillae, but that finding was an artifact caused by classifying subjects by both threshold and suprathreshold PROP bitterness. In fact, we excluded subjects with discordant results, such as those with nontaster thresholds who tasted PROP as fairly bitter, but we now know that those AVI/AVI individuals with the most fungiform papillae taste PROP as fairly bitter. These individuals are supertasters for many oral stimuli, but not for those that bind to T2R38 (e.g., PTC/PROP). *T2R38* variation fails to account for differences in perceived intensity because it fails to account for differences in oral anatomy.

The term supertaster was originally applied to those individuals who perceived the most intense taste sensations from a variety of taste stimuli, including PROP. We continue to support this view; taster status should reflect responses to multiple oral sensory cues. Because many oral sensations are influenced by anatomy, it might seem that anatomy is more accurate than PROP bitterness for classification, but pathology complicates the picture because damage to the taste system can alter oral perception while leaving fungiform papillae intact. In truth, anatomy, genetics and pathology help us to determine the underlying basis of oral sensation, but psychophysical assessment of perceived intensity remains the critical measure of oral sensory function – and the only way to identify supertasters. PROP

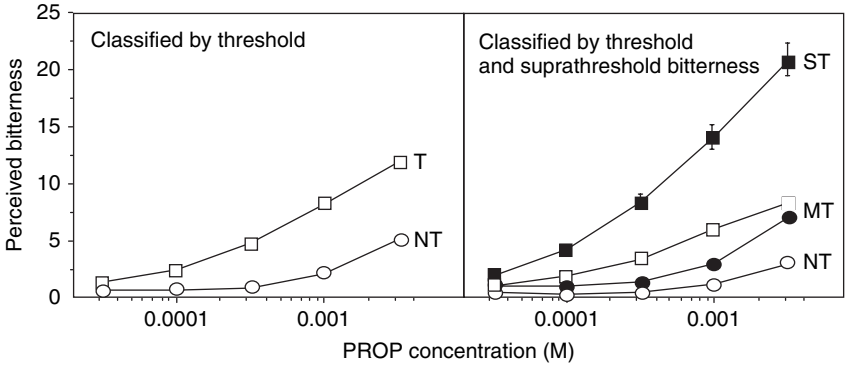

Figure 1 Bitterness of PROP (±SE) assessed with magnitude matching (i.e., magnitude estimation relative to a tone standard). The left panel shows the PROP functions for individuals with PROP thresholds > 0.0002 M (i.e., nontasters, NT, indicated by circles) and those with thresholds < 0.0001 M (i.e., tasters, T, indicated by squares). PROP thresholds strongly reflect different *T2R38* genotypes: NTs express AVI/AVI; Ts express PAV/AVI or PAV/PAV. The right panel shows the same groups subdivided into two groups each: those who tasted the least bitterness from PROP (open symbols) and those who tasted the most bitterness from PROP (filled symbols). The resulting intermediate function (i.e., medium tasters, MT) reflects a combination of PAV/PAV, PAV/AVI, and AVI/AVI genotypes. Data from Bartoshuk, L. M. 2000. Comparing sensory experiences across individuals: recent psychophysical advances illuminate genetic variation in taste perception. Chem. Senses 25, 447–460.

bitterness may provide only one picture of oral sensation, but it is quite a good picture because it represents the combined influences of *T2R38* genotype, fungiform papilla density, and disease. Oral sensation may be influenced by additional factors with uncertain impact (e.g., hormones, trophic factors, other taste/tactile genes), but PROP bitterness has proven valuable in identifying relationships between taste intensity, dietary choice, and long-term health outcomes (see below). That said, there is nothing intrinsically special about PTC/PROP except that it is a probe stimulus – one that elicits highly variable responses that often show strong agreement with other oral stimuli.

Because the functions of PROP bitterness across concentration diverge (right panel), the most accurate way to sort individuals based on PROP bitterness is to use the highest practical concentration; consistent with Figure 1, we typically use a 0.0032 M solution. An alternative to testing with PROP solutions is to use impregnated filter papers, similar to those used by Blakeslee A. F. and Fox A. L. (1932). To produce the most intense bitter taste possible with a paper test, we soak small pieces of filter paper (3 cm diameter, Whatman #1) in a saturated PROP solution (e.g., Bartoshuk, L. M. *et al.*, 2002), yielding ~1.6 mg PROP per paper. These PROP papers produce similar variability in perceived bitterness as a solution of 0.0032 M PROP.

4.20.2.6 Supertasters and Flavor

When food is consumed, the sensations we know as flavor result from mixtures of taste and oral somatosensory cues, as well as olfactory sensations produced when chewing and swallowing force food odors behind the palate and into the nasal cavity. These odor sensations are called retronasal to distinguish them from environmental odors that are sniffed, or orthonasal olfaction. Although both types of odor cues stimulate the same olfactory receptors high in the nasal cavity, retronasal olfaction is perceptually localized to the mouth and orthonasal olfaction to the nose; the two are processed in related but distinct brain regions (Small, D. M. and Jones-Gotman, M., 2001). For many years, the localization of retronasal olfaction to the mouth was thought to be mediated by oral touch (Hollingworth, H. L. and Poffenberger, A. T., 1917), but we now know that taste plays a critical role as well. If the chorda tympani taste nerve is anesthetized on one side of the mouth, retronasal olfactory cues are less intense and appear to arise from the unanesthetized side of the mouth (Fast, K. *et al.*, 2000; Snyder, D. J. *et al.*, 2001). This association explains a curious clinical phenomenon: some patients with compromised taste and oral touch report a normal ability to smell, yet they claim that flavors are diminished or absent. The brain appears to rely on the simultaneous presence of multiple cues to determine how to process incoming olfactory information – odor + sniffing = orthonasal olfaction; odor + taste + oral touch + oromotor activity = retronasal olfaction. In patients with normal smell but damaged innervation of the oral cavity, food-related odors may fail to be discriminated as retronasal because the concomitant oral cues that identify odor input as coming from the mouth are absent or reduced.

Connections between taste and retronasal olfaction suggest that perceptual differences associated with oral sensory genetics, anatomy, and pathology should extend to flavor perception; not surprisingly, supertasters perceive more intense flavors than do nontasters (Duffy, V. B. *et al.*, 2003; Bartoshuk, L. M. *et al.*, 2005a). This finding helps to explain interesting curiosities (e.g., chefs are more likely to be supertasters than chance would predict; Bartoshuk, L. M. *et al.*, 2004a), but more importantly, it contributes to robust differences in food behavior.

4.20.3 Implications of Oral Sensory Variation for Nutrition and Health

Food preferences influence food intake. Because diet is an important risk factor for a variety of chronic diseases, we have found that oral sensory variation is associated with several of these diseases. The methodological advances we have described enabled the discovery of these associations.

4.20.3.1 Cancer Risk

Links between PTC/PROP tasting and cancer first appeared some years ago (e.g., Milunicová, A. *et al.*, 1969), but more recent studies have specifically targeted oral sensory variation as a potential contributor to cancer risk. The bitter tastes of phytonutrients with cancer-preventive properties can be a barrier to their intake (Drewnowski, A. and Gomez-Carneros, C., 2000). PROP tasting is associated with reduced vegetable intake (Basson, M. D. *et al.*, 2005; Dinehart, M. E. *et al.*, 2006; Bell, K. I. and Tepper, B. J., 2006; Sandell, M. A. and Breslin, P. A., 2006). Those

who taste PROP as most bitter reported the lowest preferences for traditionally disliked vegetables (e.g., Brussels sprouts, kale) because they taste more bitter and less sweet (Dinehart, M. E. *et al.*, 2006). One of the risk factors for colon cancer is low vegetable intake (McCullough, M. L. *et al.*, 2003), and data from routine colonoscopies show that men who tasted PROP as most bitter had the most colonic polyps (Basson, M. D. *et al.*, 2005).

4.20.3.2 Cardiovascular Disease Risk

Body mass (BMI) is an important risk factor for cardiovascular disease. The first data linking BMI to PROP tasting came from Fischer (Fischer, R. *et al.*, 1966), who used thresholds for PTC and quinine to show that thinner individuals tended to be tasters. Recent work supports this early observation and suggests that those who taste less bitterness from PROP and other compounds have dietary preferences that support increased energy intake (e.g., higher preferences for fats, sweets, alcohol). For example, overweight (but not obese) middle-aged and elderly individuals tend to find PROP less bitter (Lucchina, L. *et al.*, 1995; Tepper, B. J. and Ullrich, N. V., 2001; Duffy, V. B. *et al.*, 2004b; Duffy, V. B., 2004; Goldstein, G. L. *et al.*, 2005).

Taste pathology appears to interact with genetic variability to affect BMI over time. Diminished bitter taste on the anterior tongue suggests damage to the chorda tympani taste nerve; both are associated with higher BMI (Lanier, S. A. *et al.*, 2005a). Severe middle ear infections may permanently damage the chorda tympani nerve as it traverses the middle ear, and prior histories of such infection are associated with increased BMI, especially in PROP supertasters (Tanasescu, M. *et al.*, 2000; Snyder, D. J. *et al.*, 2003; Bartoshuk, L. M. *et al.*, 2006a).

4.20.3.3 Alcohol Intake

Suggestions that PTC/PROP nontasters are most likely to abuse alcohol date back many years (e.g., Driscoll, K. E. *et al.*, 2006). The sensory properties of alcohol vary with PROP status: supertasters perceive the most intense bitterness and oral burn from alcoholic beverages, and so they like and consume them least (Bartoshuk, L. M., 1993; Duffy, V. B. *et al.*, 2004a; 2004c). Similar to the results observed with vegetables, supertasters find alcoholic beverages more bitter and less sweet than do nontasters (Lanier, S. A. *et al.*, 2005b).

4.20.3.4 Smoking

As with so many health associations related to PTC/PROP, nontasting was first associated with tobacco use by Fischer (Fischer, R. *et al.*, 1963). Modern studies support these early observations (e.g., Snedecor, C. M. *et al.*, 2006), suggesting that supertasters smoke the least (Snyder, D. J. *et al.*, 2005).

4.20.3.5 Future Interventions?

Taste blindness appears to explain some of the widespread variation in food choice. Accordingly, dietary recommendations that account for differences in oral sensation may promote food enjoyment and healthier dietary habits. While supertasters may benefit from oral sensory hindrances to overconsuming alcohol, sweets, and fats, they may have less desire to consume recommended intakes of vegetables. Manipulations that reduce vegetable bitterness (e.g., bitterness inhibition; Ming, D. *et al.*, 1999) may increase preferences for these important foods. Meanwhile, nontasters experience fewer negative sensory experiences from vegetables, but may benefit from dietary counseling to curb alcohol and carbohydrate intake, consume healthful dietary fats, and balance energy intake with physical activity. In short, understanding the behavioral implications of oral sensory variation permits us to discover effective interventions for improved health.

Glossary

KCl Potassium chloride.
LiCl Lithium chloride.
Na Sodium.
NaCl Sodium chloride; salt.

Sodium chloride (NaCl: herein referred to as salt unless otherwise noted) has played a central role in human society throughout history. As a highly valued commodity, wars have been fought to control salt access and availability, and it has served as a major basis for taxation for millennia (see Gandhi, M., 1930 for example). People have been paid in salt (salaries) and salt has been transported, sometimes requiring considerable effort and expense, across long distances (reviews: Denton, D., 1982; Kurlansky, M., 2002).

Until recently, a major problem for many people has been to obtain sufficient salt, both for themselves and also for their domestic animals, especially herbivorous ones that cannot obtain sufficient quantities of sodium (Na) from most plants. Times have changed, however, and the salt problem in much of today's world is not one of insufficiency, but of excess.

In this essay, we do not address health implications of high salt consumption; these are covered in numerous reviews and commentaries (e.g., Taubes, G., 1998; Sacks, F. M. *et al.*, 2001; Alderman, M. H., 2002; Hooper, L. *et al.*, 2002; De Wardener, H. E. *et al.*, 2004; Karppanen, H. and Mervaalo, E., 2006). The consensus is that intake of too much salt – exactly what constitutes too much for any given individual likely depends on many factors – is unhealthy for at least some proportion of the population. Consequently, achieving a more thorough understanding of salt taste, including how it is detected, the role it plays in food palatability, and how salt intake may be modified, carries public health implications. A better understanding of all aspects of salt taste is thus a necessity.

In what follows, we discuss four topics. First, we focus on how salt in the mouth evokes the sensation of saltiness. As will be shown, our knowledge of this area has advanced greatly over the past years but remains incomplete. Second, we discuss why people seem to like salt so much. This section considers both innate and acquired factors. In the third part, we consider the varied reasons for adding salt to human foods. Although these sections primarily address human salt taste and consumption, issues relevant to other animals will sometimes be raised. The final section provides an overview of strategies that might be employed to address the public health mandate to reduce salt intake.

4.21.1 What Makes Salt Taste Salty?

NaCl and LiCl (lithium chloride) are the only two substances that taste almost purely salty, lacking virtually any bitter, sour, sweet, or umami quality. Of the sodium salts, several, such as Na-acetate, are predominantly salty but weakly so, while most others

taste salty and something else, usually bitter. A few other compounds are salty with additional taste characteristics. For example, KCl is quite salty but also bitter, particularly so to some people. A small number of amino acids have a salty taste component. Nevertheless, it is striking how few salty compounds exist, and of these, how even fewer are purely salty. This paucity of salty stimuli contrasts starkly with bitter and even sweet taste, for each of which there are numerous and diverse molecular stimulants. These observations suggest a highly specific mechanism for salty taste detection. And since the primary ion in salty taste is thought to be Na (Bartoshuk, L. M., 1980), this mechanism must be specific to sodium.

A major advance in our understanding of salt taste mechanisms was made independently in the early 1980s by Schiffman S. and colleagues (Schiffman, S. S. *et al.*, 1983) and DeSimone J. and colleagues (DeSimone, J. A. *et al.*, 1981). These investigators hypothesized that the Na taste recognition mechanism might be the same or very similar to mechanisms for sodium recognition in other parts of the body, particularly the kidneys. Following this logic, dissociated Na dissolved in saliva was postulated to activate a Na-specific ion channel. Over the ensuing 25 years, this important insight has received a substantial body of support from biophysical, physiological, and sensory studies that employed mainly animal models such as rats, mice, and dogs. Particularly telling support came from studies demonstrating that a major component of salt taste transduction is inhibited by amiloride, a diuretic that blocks sodium channels. However, most of these studies also indicated the additional existence of a nonamiloride-suppressible component to salt taste transduction (see, e.g., Geran, L. C. and Spector, A. C., 2000). The nature of this second element remains obscure, although it might involve a nonspecific vanilloid receptor-1 analog (Lyall, V. *et al.*, 2004).

The sodium ion channel scenario is elegant in its simplicity and intuitive appeal. In particular, it can account for the specificity of Na as the main component of saltiness perception. Moreover, sodium ion channels have been implicated in the salt taste perception of animal models ranging from sheep to rats to flies (e.g., Liu, L. *et al.*, 2003). Nevertheless, the hypothesis is not completely compelling. Although some of the original data from human psychophysical studies showed that amiloride reduced human perception of salty taste, subsequent studies have been inconsistent. Indeed, in an extremely thorough review of this literature, Halpern concluded that amiloride has little or no effect on human perception of NaCl saltiness (Halpern, B. P., 1998). These human data are quite puzzling in the face of the overwhelming evidence for an amiloride effect to reduce salt taste perception in other animal models.

Perhaps this should not be so surprising; species differences are common for other taste transduction mechanisms, as they are in many other biological areas. Yet given the fundamental nature of salt taste, along with the widespread evidence for involvement of a sodium channel in so many species, it seems implausible that humans would possess a completely novel mechanism for detecting NaCl. Perhaps the channel is sufficiently altered in humans that amiloride is ineffective; this would account for the fact that some human sodium channels are not amiloride blockable. What is needed to fully understand human salt taste is a comprehensive explanation of the molecular mechanisms that underlie its detection. While this is not yet available, it is likely to be forthcoming quite soon.

As noted above, salt taste transduction also includes an amiloride-insensitive component, which again is not well understood (Halpern, B. P., 1998). Activation of this component, which is not specific to sodium, may not be perceived as fully or even partially salty. Nevertheless, identification of this mechanism and its function will be necessary for a full understanding of the molecular basis for salt taste.

4.21.2 Why Do We Like the Taste of Salt?

Attempts to answer this complicated question are generally addressed at two levels: one involving true physiological salt need and the second involving need-free salt intake.

4.21.2.1 Liking for Salt: Sodium Need

It is widely assumed that the very existence of a mechanism to specifically detect Na is due to the special role Na plays in animal biology. This rationale has been thoroughly reviewed elsewhere (Denton, D., 1982) and includes the importance of Na in nerve conduction, energy release, and acid–base balance. Moreover, since Na is not evenly distributed in nature and is present in very low concentrations in many plants, it is assumed that a

specific means to detect its presence would be highly adaptive. These theoretical arguments are supported by the widespread existence across species of mechanisms for detecting salt, by salt taste's apparent status as one of a small group of basic tastes in many organisms, and by the motivating effects of salt taste, particularly when Na is scarce (McBurney, D. H. and Gent, J. F., 1979).

This last point requires elaboration. A tremendous number of observational and experimental studies (again reviewed with great scholarship by Denton, D., 1982; for a more recent review see Schulkin, J., 1991) demonstrate that a sodium-deficient animal, especially an herbivore or omnivore, will go to great lengths to obtain Na, using salty taste to detect sources of Na. This need-based search for and consumption of salt has provided a model system that demonstrates innate and specific mechanisms for detecting Na and has identified some of the hormonal substrates that underlie need-based salt appetite. This vast area of research is difficult to summarize, but apparently Na depletion elicits changes in hormones and central neural system organization that over time alter avidity for the taste of salt. Indeed, the taste quality elicited by salt may change as a function of sodium depletion and hence need (for review, see McCaughey, S. A. and Scott, T. R., 1998). A peripheral component may also contribute to increased avidity for Na in the face of need, as Na depletion may alter salt taste transduction mechanisms (Contreras, R. J. and Frank, M., 1979) in addition to central mechanisms regulating the avidity for salt. Put simply, Na depletion seems to make salt taste both better and different in animal models such as rodents and sheep.

Once again, species differences are apparent. As might be anticipated based on a meat diet naturally rich in sodium, carnivores may not respond physiologically or behaviorally to Na depletion in the same ways that omnivores and herbivores do. Perhaps carnivores such as dogs and cats never experience the consequences of Na depletion. As meat-eating animals, they either ingest sufficient food to survive, consequently ensuring adequate Na, or they die of starvation.

A more puzzling species difference again involves humans. The evidence that Na depletion in adult humans stimulates a specific, intense desire for the taste of salt is weak (Beauchamp, G. K., 1991). Although some human experimental studies indicate that Na loss is followed by an elevation in salt liking, this does not truly mimic the responses of animal models, where extreme avidity follows depletion. A partial explanation may be that human experimental studies cannot induce the same degree of depletion routinely employed in animal model studies.

In one area, species differences may not exist. When Na depletion occurs very early in human life as a result of varied clinical conditions, a profound elevation in the desire for salt occurs, similar to that seen in experimental rodent models. For obvious reasons, there are no experimental studies of early Na depletion in humans; however, the weight of clinical evidence (Beauchamp, G. K. *et al.*, 1991) indicates that such heightened avidity is remarkably persistent. This observation is mirrored in some animal model studies (e.g., Thaw, A. K. *et al.*, 2000), demonstrating a permanent elevation of salt taste avidity following early Na depletion. The relative roles of central and peripheral changes in modulating this effect remain unknown.

4.21.2.2 Liking for Salt: Need-Free Consumption

Although it makes some evolutionary sense that many species would develop mechanisms to enable detection of environmental Na and facilitate ingestion under conditions of depletion, why do they consume it avidly when not deficient? More specifically, why do humans in almost all developed societies, who are probably never truly sodium deficient, so like their food with substantial added salt?

Two explanations have been proffered. The first suggests that herbivores and some omnivores have an innate liking for the taste of salt. According to this rationale, it is to an organism's benefit to consume salt when it is available. There is no cost for this behavior, with the exception of some adult-onset diseases, as excess sodium is easily removed by the kidneys. Furthermore, it has been hypothesized that high Na intake may reflect evolutionary pressure to protect against sudden dehydration (Fessler, D. M. T., 2003). A problem with this line of argument centers on the fact that sodium cannot be stored. What then is the advantage of consuming salt in excess whenever it is available? Perhaps, this behavior allows animals learn its location so as to be able to quickly locate it in preparation, from an evolutionary perspective, for later deficits. Indeed, sodium-deprived rats do use learned associations between environmental cues and salt taste to guide them to locations where they have previously ingested salt (Stouffer, E. M. and White, N. M., 2005).

The second explanation is that individual exposure to salt, particularly early exposure, results in a heightened desire or avidity (e.g., Smirga, M. *et al.*, 2002). This is a commonly-held belief among nutritionists, dieticians, physicians, and others (e.g., MacGregor, G. A. and de Wardener, H. E., 1998). But this explanation raises yet another question. Why should a taste experienced in infancy or even adulthood take on heightened value? This is often called taste imprinting but, unlike classic imprinting where the animal learns important characteristics of its parent, the adaptive value of taste imprinting is obscure, particularly for omnivorous species like humans or rats.

Experimental studies in animal models and humans provide several examples of effects of early dietary exposure to salt on subsequent perception and preference. As noted previously, sodium depletion early in life may cause an elevation of salt preference. The opposite – high sodium consumption early in life – also has been reported to have modest effects in heightening later preferences (Contreras, R. J. and Kosten, T., 1983). Furthermore, amniotic fluid, saliva, and milk all contain sodium, consumption of which could establish or heighten a preference, and many studies with rodent models, particularly rats, demonstrate that salt solutions around isotonicity are avidly consumed on first presentation.

As with most arguments pitting innateness versus learning, this dichotomy is almost assuredly false. Liking for salt and salty foods is surely the result of an interaction between innate and acquired information. Human infants at birth are either indifferent to salt or reject it, particularly at hypertonic concentrations (Beauchamp, G. K. *et al.*, 1986). By approximately 4–6 months of age, infants show a preference (relative to plain water) for low-to-moderate saline solutions around the level of isotonicity. This age-related hedonic shift may represent in part the maturation of an innate transductive or neurological mechanism. Some rodent studies have shown the ability to detect salty taste matures postnatally (for review, see Hill, D.L. and Mistretta, C.M., 1990); this may also be the case for humans. Prior exposure to foods containing salt may modulate this developmental change (e.g., Harris, G. and Booth, D. A., 1985). We have recently found (Stein, L. J. *et al.*, in preparation) that infants fed starchy foods between months 2 and 6 of life show heightened salt preferences relative to infants not exposed to these foods. Since one characteristic accompanying ingestion of starchy foods is likely a substantial exposure to salt, it is possible that this difference represents effects of prior exposure to salt. Perhaps, salt exposure during a critical period of receptive element maturation permanently alters peripheral and/or central structures and is thereby particularly potent in establishing childhood and perhaps even adult habits of intake. Alternatively, the heightened salt preference could reflect a shift in response to increased salt in the diet, similar to what is observed in adults (Bertino, M. *et al.*, 1986; see also discussion below). This is surely an area that should be investigated since it has major public health implications.

Although liking for salt in foods by children and adults is virtually universal, there are substantial individual differences. The degree to which genetic differences in salt taste perception could underlie these differences is unknown, but as the human salt taste mechanism(s) becomes better characterized, the influence of genetic variation will simultaneously become more clear.

In addition to probable effects of early exposure, environmental factors play a major role in determining salt avidity and consumption. The existence of societies where salt intake is very low has been interpreted to indicate that higher intake, such as that of Western societies, is the result of habit and commercial interests (e.g., MacGregor, G. A. and de Wardener, H. E., 1998). However, in most of these societies, low salt intake reflects low availability; wherever salt is inexpensive and widely available, it is noteworthy that most cultures consume roughly the same amount (see data in Intersalt Cooperative Research Group, 1988). This observation leads one to wonder whether there remains an unidentified (physiological?) explanation for human salt consumption. This question was raised many years ago (Bunge, G., 1902; Kaunitz, H., 1956) and remains worthy of consideration, particularly in light of calls for substantial population-wide reduction in salt consumption.

4.21.3 What Are the Functions of Salt in Food?

In the foregoing, it has been implicitly assumed that the proximate reason humans avidly consume Na is because we like the experience of the salty taste. This is undoubtedly part of the reason for modern human salt consumption, but surely not the only one, for salt plays many other roles in human food and nutrition.

Virtually all the salt people consume is in or on food; very few individuals eat pure salt outside that

Table 1 Number of recipes for which salt is called for in La Cuisine de France (Turgeon, C., 1964)

Food group	*Number of recipes*	*Number calling for salt*	*Number calling for other salty ingredients*	*% calling for salt*
Vegetables	142	131	11	100
Soups	51	51	0	100
Sauces	26	26	0	100
Starches (potato, rice, pasta, etc.)	59	57	2	100
Pastry[a]	136	70	10	58

[a]Many of the pastry recipes are for frosting-like items that are mainly sugar.
Note: Not tabulated are entrees, eggs, fish, poultry and game, meat, salads, desserts, and wine. Many of these use or are served with the items in the table.

context. In foods, salt has several technical functions (Man, C. M. D., 2007). It is an excellent preservative, preventing bacterial growth. It also serves structural functions during cooking and food processing by interacting with other ingredients to affect the texture and color of food. In addition to salt's functional benefits, it has a very significant additional strong point for both industry and the home cook: it is cheap. Consequently, any acceptable salt alternative must not only taste good and function as well as salt, but must also be inexpensive.

In addition to these functional features that make salt so important in foods, salt plays a sensory role over and above making food taste salty. Consider again bread and bread products. The salt in these makes up the single largest source of sodium consumed in the US diet; yet, we typically do not perceive bread as salty. Bread without salt tastes insipid or bad; when salt is added, the flavor is enhanced without making the bread taste salty. Thus salt, when added to food, must have functions other than adding saltiness. What are they?

One supposition is that the sense of taste imparts not only a quality, but also a sensation of quantity, amount, or bulk. It is difficult to know how to experimentally approach this concept; something similar to mouthfeel might be involved. It is as if taste stimuli (umami and sweet perhaps having some of the same characteristics as salt) might also interact with tactile fibers or other chemosensory structures to give a sense that the food has substance.

If this idea of mouthfeel is hard to encompass, yet another function of salt is better established. Sodium is an outstanding inhibitor of certain bitter-tasting compounds (Breslin, P. A. S. and Beauchamp, G. K., 1995). We have shown (Breslin, P. A. S. and Beauchamp, G. K., 1997) that a sodium salt added to a mixture of bitter and sweet suppresses the bitterness, thereby releasing the sweet from inhibition. The overall sensory effect in the three-component model system is to enhance sweetness. We suggest that this can help explain why salt is added to so many foods when the intent is not to add saltiness: the salt suppresses off tastes and enhances good ones. Indeed, in a survey of recipes from one traditional French cook book (Turgeon, C., 1964) (Table 1), we found that most included either salt or a condiment-like olives that is high in salt. Clearly, the value of salt to food is demonstrated by its frequent use both by the home cook and by the multinational food companies.

4.21.4 What Can Be Done to Reduce Salt Consumption?

If salt reduction is the goal, what reasonable strategies are possible? There appear to be two approaches to reducing sodium consumption. In both salt is removed from foods; in the first, it is claimed that people would adjust to or at least tolerate the changes in taste (if the nontaste functions could be accounted for by other means), whereas in the second, an alternative taste-active substance is added to offset the loss of salt.

Consider the first strategy, which assumes that excess intake (relative to known physiological need) is due to habit and that habits can be changed. Clinical and anecdotal literature (see Beauchamp, G. K., 1991) reveal that when people undertake a low-sodium diet, the immediate response is misery. However, the lower sodium diet eventually becomes accepted, and in fact, foods containing the previous amount of salt are perceived as too salty (e.g., Stefansson, V., 1946). Many years ago, we provided experimental evidence to support this observation

(Bertino, M. *et al.*, 1983). After assuming a diet with about a 50% reduction in sodium content for 2–3 months, volunteers came to prefer their food with lower salt levels. They acclimated to this diet. We also showed (Bertino, M. *et al.*, 1986) that preference could be moved in the other direction: when people were put on a higher salt diet, they began to like more concentrated salt in their foods.

This evidence supports the view that if somehow we were to all undertake a low sodium diet, it would soon come to be the norm and no one would notice or feel deprived. But is this really possible? One widely recommended strategy is for food suppliers to gradually reduce the salt in foods so that the change is not noticed. Indeed, it appears that one can reduce the salt in some foods as much as 25% without consumers being aware (Girgis, S. *et al.*, 2003). But if people do not notice the reduction, will their taste preference change? And without a change in preference, can significant reductions really be obtained? Another issue that has not been experimentally addressed is whether one could lower the expected level of salt in one segment of the diet (e.g., commercial soups) and not the remainder of the foods. Would people come to prefer a lowered salt level in the single food if the overall levels were not correspondingly lowered or would they just choose not to eat as much soup (or add salt to it)? I am aware of no research that bears on this point. Finally, how would one deal with the nontaste functions of salt discussed above?

In summary, there is reason to believe that sodium intake could be successfully lowered through a unified dietary reduction in salt (assuming that the drive to consume salt in excess of need referred to in the previous section does not exist), but many practical difficulties need to be addressed.

Diabetics should not consume sugar in excess. Until fairly recently, this meant that they could not have sweeteners in their diet. Then came the introduction of saccharin and other alternative sweeteners. Could there be a saccharin or aspartame or sucralose for salt? Unlike the many molecules that function as alternative sweeteners, very few purely salty compounds have been identified. Indeed, given what we know about the receptor mechanisms for sweet and salty taste, it is quite likely that few or no such compounds will be found. Sweet taste recognition involves a classical seven-transmembrane G-coupled receptor system. It acts similarly to a lock and key, and apparently any molecule having the key's features will taste sweet (see Nelson, G. *et al.*, 2001; reviews: Margolskee, R. R., 2002; Kim, U.-K. *et al.*, 2004). In marked contrast, as discussed above, the high specificity of the sodium channel involved in salt taste transduction may mandate that no sodium-free salt taste substitutes exist.

Amiloride studies inform us that it is possible to modify the intensity of saltiness (at least in animal models). This leads to the question: If saltiness can be inhibited, can it also be enhanced? Might it be possible to find a compound or compounds that, when added to a reduced sodium food, make that food taste acceptably salty? Some amino acids and amino acid salts have this property, thus demonstrating proof of principle (Tamura, M. *et al.*, 1989; Lee, T. D., 1992; Riha III, W. E. *et al.*, 1997). What is needed is a concerted effort, most efficiently using the (yet unidentified) human salt receptor as a screening device, to search for such molecules. Of course, if one is found, many practical problems will arise. Is it safe? Does it have the other functions of salt, for example the bitter blocking activity? Is it sufficiently inexpensive? Will people accept a new chemical in their food? In spite of these problems, the search for a salt enhancer is worthwhile and has promise.

4.21.5 Final Comment

There is still much to learn about how salt taste is perceived and what factors are responsible for preferences for salt in foods. Given the apparent role of excess salt intake in human disease, primarily essential hypertension, it is imperative that this gap in our knowledge be closed.

4.22.1 Introduction

Researchers studying sensation and perception face the daunting task of making inferences about the internal experience of the subject without the benefit of direct measurement. In humans, perception is sometimes inferred through verbal report. This is not possible in nonhuman animals, from which the primary neurobiological database derives. Consequently, perceptual processes must be assessed through other behavioral means. This poses significant methodological and conceptual challenges, but is an absolutely

essential component in any attempt to understand the neural principles underlying perception. Indeed, the strategic use of well-designed and complementary behavioral procedures, coupled with theoretically relevant manipulations of the nervous system, can lead to rich insights into the relatively concealed workings of our own sensory machinery.

Comparisons of the consequences of neural manipulations on the performance of animals tested on diverse behavioral tasks have historically provided powerful breakthroughs in understanding sensory function. A vivid example of this was the use of multiple visual tasks to better define the blindness caused by tectal lesions in hamsters (Schneider, G. E., 1969). Following such lesions, hamsters located food only by touch and smell, and did not orient their heads to motion, but did learn to associate a visual cue with the availability of water. In contrast, animals with lesions of the primary visual cortex located food by sight and oriented their heads in response to moving stimuli, but did not learn to associate a visual cue with water if the stimulus was sufficiently complex. This study, and others like it, highlights the danger of misinterpreting functional deficits, or lack thereof, following neural manipulations, if the scope of the behavioral analysis is limited. In other words, if only a single behavioral task had been employed to assess the effects of the lesion, different conclusions may have been reached regarding the functional use of sight. Without question, such experiments helped refine the concept of blindness and have contributed greatly to our view of the brain as a parallel processor.

In this vein, the purpose of this chapter is to discuss some basic interpretive properties of standard behavioral tasks that have been, and can be, used to infer the taste capabilities of nonhuman animal subjects and to provide some examples of how several of these paradigms have been successfully used in efforts to reveal the functional organization of the gustatory system.

4.22.2 Domains of Taste Function

Taste function can be heuristically divided into at least three domains (see Pfaffmann, C. *et al.*, 1979; Norgren, R., 1985; Scott, T. R. and Mark, G. P., 1986; Spector, A. C., 2000). The sensory-discriminative domain refers to the processes that allow animals to discriminate between taste compounds. This function can be subdivided into intensity, providing information regarding the amount of the stimulus, and quality, providing information about the identity of the stimulus. The motivational domain refers to processes that promote or discourage ingestion of chemical substances. This function can be subdivided into an appetitive/avoidance component, which refers to actions that bring the animal closer to, or take the animal further from, the stimulus, and a consummatory/rejection component, which refers to reflex-like oromotor movements that lead to the ingestion or expulsion of stimuli contacting taste receptors (Craig, W., 1918; see also Grill, H. J. *et al.*, 1987; Berridge, K. C., 2004). Finally, the physiological domain refers to the ability of taste stimuli to trigger autonomic responses such as salivation (e.g., Pavlov, I. P., 1902).

In mammals, taste buds are distributed throughout the oral cavity in distinct fields each innervated by a different branch of three cranial nerves (Bradley, R. M., 1971; Miller, I. J., Jr., 1977; Travers, S. P. and Nicklas, K., 1990). In the central nervous system, gustatory projections form two divergent pathways as they ascend from the caudal brainstem to the forebrain – a thalamocortical pathway, characteristic of many sensory systems, and a ventral forebrain pathway, involving the amygdala, hypothalamus, and other structures (see Norgren, R., 1992; Travers, S. P., 1993; Norgren, R., 1995). Thus, the anatomical organization of the gustatory system invites speculation regarding the functional significance of these neural circuits. One effective strategy that has been used to uncover the relationship between nervous system structures and gustatory function is to alter the flow of information along these pathways and assess the consequences on taste-related behavioral tasks. Several decades of such experiments have taught us that a single behavioral measure is not sufficient to capture the full impact of a given manipulation on gustatory function. Just as blindness can be a relative term, so can aguesia. Competence or impairment on one behavioral task involving taste stimuli does not necessarily predict the same level of performance on another after a given experimental manipulation of the nervous system.

Some examples of such functional dissociations can be found in the following pages. The remainder of Section 4.22.3 will briefly review some of the methodological and interpretive properties of various behavioral paradigms used to assess gustatory processes in animal models, and Section 4.22.4 will illustrate the successful use of such procedures in neurobiological studies.

4.22.3 Behavioral Assessment of Taste Function

The assessment of taste function in animals requires careful consideration of the methodological features of the behavioral procedures used. Performance in some behavioral paradigms reflects the outcome of processes involving more than one functional domain (Table 1). These behavioral paradigms differ in some fundamental ways.

Procedures that involve the measurement of intake over prolonged periods of stimulus presentation (e.g., two-bottle preference test) are governed partly by the affective potency of the stimulus, but are also vulnerable to the influence of postingestive events (e.g., McCleary, R. A., 1953; Shuford, E., Jr., 1959; Mook, D. G., 1963; Rabe, E. F. and Corbit, J. D., 1973; Weingarten, H. P. and Watson, S. D., 1982; Nissenbaum, J. W. and Sclafani, A., 1987a). Intake tests involving the use of the sham drinking preparation (in which the ingested content flows out of an open gastric cannula) provide greater confidence that taste processing – or at least orosensory processing – guides behavior (e.g., Davis, J. D. and Campbell, C. S., 1973; Weingarten, H. P. and Watson, S. D., 1982; Schneider, L. H. *et al.*, 1986; Nissenbaum, J. W. and Sclafani, A., 1987a). Similarly, the presentation of fluids in brief-access trials, which minimize the influence of postingestive receptor systems during the response, can be used to assess the motivational characteristics (i.e., affective potency) of taste stimuli (see Young, P. T., 1952; Young, P. T. and Madsen, C. H., Jr., 1963; Grill, H. J. and Berridge, K. C., 1985). These procedures involve both an appetitive/avoidance component and a consummatory/rejection component. Other tasks allow investigators to assess the appetitive/avoidance component (e.g., a progressive ratio procedure) independent of the consummatory/rejection component and vice versa (e.g., an oromotor taste reactivity procedure).

In still other procedures, taste compounds are used as discriminative stimuli in operant-conditioning procedures or as conditioned stimuli in classical conditioning paradigms (e.g., Koh, S. D. and Teitelbaum, P., 1961; Morrison, G. R. and Norrison, W. 1966; Morrison, G. R., 1967; Slotnick, B. M., 1982; Spector, A. C. *et al.*, 1990b; Stapleton, J. R. *et al.*, 2002). These tasks provide a means by which sensory-discriminative taste function can be assessed separately from the affective properties of a stimulus. For example, hydrochloric acid or citric acid, quinine, and high concentrations of sodium chloride (NaCl), are all avoided by rats in intake and brief-access taste tests, but rats can be trained to discriminate these compounds in operant or classical conditioning paradigms (Morrison, G. R., 1967; Nowlis, G. H. *et al.*, 1980).

Regardless of the behavioral procedure employed, the potential for nongustatory cues associated with other chemosensory receptor systems must be considered. Perhaps the most vexing of these signals arises from stimulation of the trigeminal and olfactory systems, particularly at higher stimulus concentrations. For example, the viscosity of sugar solutions or the irritant properties of salts and acids (e.g., Gilmore, M. M. and Green, B. G., 1993) produce trigeminal sensations that could potentially affect behavioral responses. Although many prototypical taste compounds have very low vapor pressures and are thus suboptimal olfactory stimuli, there is evidence that rats can detect the smell of some taste solutions (Miller, S. D. and Erickson, R. P., 1966; Van Buskirk, R. L., 1981; Rhinehart-Doty, J. A. *et al.*, 1994; Capaldi, E. D. *et al.*, 2004). In contrast, at least with certain types of stimulus delivery designs (e.g., Spector, A. C. *et al.*, 1990a), it is clear that odor cues, if present, are insufficient at maintaining normal performance in some taste-related tasks when certain gustatory nerves are transected – a neural manipulation unlikely to have any direct effect on the olfactory system (e.g., Spector, A. C. *et al.*, 1990b; Slotnick *et al.*, 1991; Spector, A. C. *et al.*, 1996b; St. John, S. J. and Spector, A. C., 1996; St. John, S. J. and Spector, A. C., 1998). In any event, such concerns often necessitate empirical assays of the contribution of extragustatory sensory cues to behavior.

4.22.3.1 Two-Bottle Preference Test

4.22.3.1.1 Procedure

In the two-bottle preference test, animals are presented with two bottles usually placed on their cages for ~24 h. One bottle contains a taste solution and the other contains water (or some other taste solution). The relative intake of the two solutions is calculated and then the bottles are refilled, the positions reversed, and the test repeated. The repetition of the test with the bottles reversed serves to offset the appearance of a solution preference that may instead reflect a position preference. The determination of preference is based on the 48 h values. If the animals are unfamiliar with having access to two bottles or to bottles of the type used for the experiment, it is advisable to present habituation trials consisting of only water in advance of the experimental tests.

In most applications of this procedure, it is the outcome of the behavioral response, intake, which is

Table 1 Functional features of behavioral taste tests

[a]Because of the specificity of responses to sodium salts in sodium-depleted animals, this test could be considered as a sensory measure of taste quality under certain conditions.
[b]Though not explicitly measured. If this test is coupled with a licking pattern analysis, then burst of licks could be considered as reflecting a strong consummatory component.
[c]The extent depends upon the duration of the test.
[d]Deprivation is not always required for unconditionally reinforcing stimuli (like sucrose).
[e]Deprivation is not required for long-duration tests (24 h, overnight, etc.).
[f]Though not explicitly measured. Trials initiated would be considered a pure appetitive measure, but the licks taken on a trial in some sense represents both appetitive and consummatory responses.
[g]Or virtually none. There is some evidence of some small amounts of nutrients passing into the duodenum during sham drinking.
[h]There may be some stimulus pairs (e.g., sucrose vs. quinine) where hedonically based taste discriminations could be possible.

measured. However, in some cases, investigators have measured licking behavior itself and have thus been able to reconstruct the pattern of drinking (e.g., LeMagnen, J. and Devos, M., 1980; Smith, J. C. and Foster, D. F., 1980; Spector, A. C. and Smith, J. C., 1984; Davis, J. D., 1989; Davis, J. D. and Smith, G. P., 1992; Davis, J. D., 1996; Spector, A. C. and St. John, S. J., 1998). When this is done in rodents, it is clear that drinking occurs in bursts of licks separated by pauses. A collection of bursts followed by a long pause could be construed as an ingestive bout or a meal if the solution is caloric. The number of bursts represents a relatively pure assessment of the appetitive behavior (i.e., initiations of drinking) and the size of a burst is heavily influenced by consummatory processes (e.g., swallowing). Thus, more refined measurement of behavior during a two-bottle preference test can provide meaningful information regarding the effects of taste on the components of motivated action.

4.22.3.1.2 Strengths

The two-bottle preference test has a long history, and thus a large body of normative data exists using this procedure. It is also relatively inexpensive, requires no customized equipment, and does not involve complicated training protocols for either animals or the staff. It is also usually amenable to testing a large number of subjects simultaneously.

4.22.3.1.3 Limitations

This test has been used to assess unconditioned and conditioned taste preferences and aversions. When used to measure unconditioned responses to taste compounds it does not provide any explicit information about the discriminative qualitative features of the stimulus (i.e., an animal might avoid both hydrochloric acid and quinine relative to water, but a similar level of avoidance does not preclude that that animal could discriminate these tastes from one another). The two-bottle preference test can provide some information about intensity, but it is difficult to discern the intensity of the stimulus independent of its hedonic characteristics because it is the latter that help drive the intake. For example, Eylam S. and Spector A. C. (2002) found that the NaCl detection thresholds measured with an operant-conditioning procedure (discussed below) were well below the concentration at which the same mice started to reliably avoid the stimulus in a two-bottle preference test. Thus, although mice could detect low concentrations of NaCl, they apparently displayed no consistent preference or aversion for them (Figure 1). In contrast, detection thresholds for

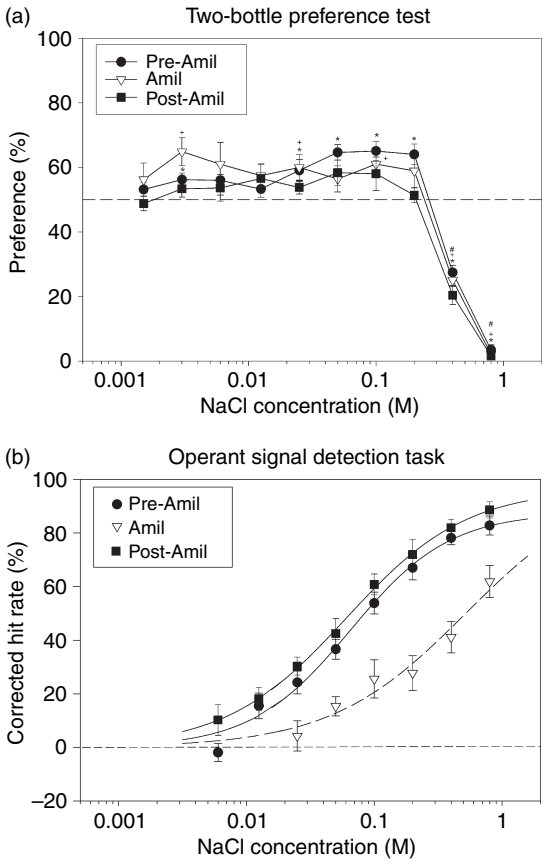

Figure 1 (a) Mean (± standard error of the mean) percentage NaCl intake by C57BL/6J mice ($n = 7$) in a 48 h two-bottle preference test in which ascending concentrations of NaCl were pitted against water in three series of tests with (Amil, open triangles) and without (preAmil, closed circles; post-Amil, closed squares) 100 μM amiloride serving as the solvent. Significant differences from 50%: * for pre-Amil, + for Amil, and # for post-Amil. These mice had been previously tested for detection thresholds in an operant signal detection task (see (b)). (b) Mean (± standard error of the mean) percentage hits on NaCl trials corrected for false alarms on water trials in an operant signal detection task as a function of NaCl concentration. The mice were tested in three phases of sessions. In the first (preAmil, filled circles) and third phase (post-Amil, filled squares), the NaCl was dissolved in water. In the second phase of sessions (Amil, open triangles), the NaCl was dissolved in 100 μM amiloride. In comparing (a) and (b) note that the preference-avoidance function is relatively flat until the concentration exceeds 0.2 M, whereas the dynamic range of responsiveness in the operant signal detection task occurs at lower concentrations. Also, amiloride had little effect on NaCl preference in these mice, but had a striking effect on NaCl detectability in the operant task. Adapted with permission from Eylam, S. and Spector, A. C. The effect of amiloride on operantly conditioned performance in an NaCl taste detection task and NaCl preference in C57BL/6J mice. Behav. Neurosci. 116, 149–159, 2002, Copyright 2002, American Psychological Association.

sucrose and glucose in mice correspond reasonably well with preference thresholds reported in the literature in mice (Bachmanov, A. A. *et al.*, 2001) likely because the affective value of these stimuli grows sharply once they are detected (see Eylam, S. and Spector, A. C., 2004). It is prudent to use the term preference threshold to indicate the concentration that subjects treat differently than water in two-bottle preference tests, and reserve the term detection threshold for concentrations discriminated from water in assays (like operant-conditioning procedures) where behavior is not dependent on hedonic evaluations.

As mentioned above, one principal shortcoming of the long-term two-bottle preference test is that postingestive events can influence intake and thus can complicate the interpretation of taste effects. For example, St. John S. J. *et al.* (2005) recently demonstrated that the dramatic increased avoidance of phenylthiocarbamide with ascending concentration in certain mouse strains was most likely due to the formation of a conditioned aversion to that compound over successive intake tests, rather than the expression of unconditioned avoidance due to its taste.

4.22.3.2 Brief-Access Taste Test

4.22.3.2.1 Procedure

In the brief-access taste test, animals are presented with very brief access to taste solutions, on the order of a few seconds, during which licking responses are measured (e.g., Young, P. T. and Trafton, C. L., 1964; Davis, J. D., 1973; Yamamoto, T. and Asai, K., 1986; Krimm, R. F. *et al.*, 1987; Smith, J. C. *et al.*, 1992; Breslin, P. A. *et al.*, 1993b; Spector, A. C. *et al.*, 1993a; 1993b; O'Keefe, G. B. *et al.*, 1994; St. John, S. J. *et al.*, 1994; Contreras, R. J. *et al.*, 1995; Markison, S. *et al.*, 1995; Spector, A. C. *et al.*, 1996b; Boughter, J. D. *et al.*, 2002; Glendinning, J. I. *et al.*, 2002; Zhang, Y. *et al.*, 2003; Dotson, C. D. and Spector, A. C., 2004). Many trials are presented during a session and responses to a variety of different solutions varying in concentration and/or solute can be tested. For normally preferred compounds, the test can be conducted in nondeprived animals, but for normally avoided compounds, the test must be conducted in fluid-deprived animals so that the subjects are highly motivated to sample the stimuli in search of water.

4.22.3.2.2 Strengths

Because immediate responses to small volumes of taste stimuli are measured, this test minimizes the influence of postingestive events on the behavior. Furthermore, the brief-access taste test can measure changes in responsiveness past the point at which preference tests reach asymptote as the concentration is raised. Because many trials are presented in a single session, full concentration–response functions can be obtained in a single test session. Random presentation minimizes order effects which are sometimes present in concentration series of longer-duration intake tests. In general, very orderly concentration–response functions are derived in the brief-access taste test, although the dynamic range of responsiveness is biased toward the higher concentrations (i.e., as with the two-bottle preference test, the concentration at which the lick rate differs from water may or may not be closely related to the detection threshold).

4.22.3.2.3 Limitations

First, like the two-bottle preference test, the brief-access taste procedure relies on the hedonic characteristics of the stimulus to drive responses and thus does not provide explicit information regarding the discriminative qualitative features of a taste compound. For example, animals will avoid licking both NaCl and quinine in a concentration-dependent manner even though they can discriminate between these stimuli in several other tasks (e.g., Morrison, G. R., 1967; Nowlis, G. H. *et al.*, 1980; Spector, A. C. *et al.*, 1993a; Cauthon, R. *et al.*, 1994; St. John, S. J. *et al.*, 1994; Spector, A. C., 1995b; Boughter, J. D. *et al.*, 2002; Glendinning, J. I. *et al.*, 2002; Geran, L. C. *et al.*, 2004).

Second, although concentration–response functions using this method are highly reliable within a given context, the context can affect the outcome. For example, the concentration–response function can be shifted to the left when an animal is tested with only one concentration per session pitted against water, rather than randomly presenting all concentrations on each day of testing (Glendinning, J. I. *et al.*, 2005).

Third, the brief-access taste test provides a measure of the affective potency of a taste stimulus, but does not clearly differentiate between appetitive/avoidance and consummatory/rejection responses. The former behavior is associated with the animal approaching the drinking spout and the latter behavior is reflexively triggered by the contact of the oral receptors with the stimulus. Although it may be possible to reconstruct the pattern of licking behavior during a trial to try to distinguish these processes, the very brief duration of the observation period (usually 5–10 s) places limitations on such an analysis. In contrast, trials initiated could be considered a measure of appetitive behavior, but this datum is also

under the influence of the postingestive properties of the stimulus and the physiological state of the animal. For example, it is likely that the more fluid-deprived an animal is, the more trials it will initiate.

Finally, and unlike a long-term preference test, the brief-access taste test must be conducted differently for normally preferred and normally avoided stimuli. Animals will not initiate trials to nonpreferred stimuli unless they are water-deprived; in contrast, water-deprived rats will lick all concentrations of preferred substances at a maximal rate (a ceiling effect). Depending on the overall goals of the research, the physiological state of testing may constrain interpretation.

4.22.3.3 Oromotor Taste Reactivity Test

4.22.3.3.1 Procedure

Chronic indwelling cannulae can be surgically implanted into the oral cavity through which taste solutions can be infused at a rate and pattern under the control of the experimenter. Oral motor and somatic responses can then be monitored (Grill, H. J. and Norgren, R., 1978c; 1978d; Grill, H. J. *et al.*, 1987; Spector, A. C. *et al.*, 1988; Brining, S. K. *et al.*, 1991; Berridge, K. C., 1996). Animals can swallow or expel the infused fluid. Ingestive responses elicited by normally preferred stimuli include tongue protrusions and low-amplitude mouth movements. Aversive responses elicited by normally avoided stimuli include gapes, chin rubs, head shakes, and forelimb flails. Generally the responses are videotaped or measured with electromyographic (EMG) electrodes placed in relevant oromotor muscles (e.g., Travers, J. *et al.*, 2000).

4.22.3.3.2 Strengths

Orofacial responses are triggered by the stimulus contacting the oral receptors and no appetitive action is necessary for stimulus delivery making the test useful for assessing consummatory/rejection behavior almost purely. In addition, because the experimenter initiates stimulation directly, there is no need for food or water deprivation to promote stimulus sampling.

The test is typically very short, on the order of a minute, precluding any substantial postingestive influence.

4.22.3.3.3 Limitations

As with the other tests described thus far, taste reactivity is dependent on the affective properties of the stimulus, and thus does not indicate the relative discriminability of stimuli or provide high-fidelity information about detection thresholds. Unlike most behavioral assays, this procedure requires a surgical procedure, albeit one that rodents tolerate well. Also, unlike most behavioral assays, the dependent variable cannot be automatically counted (e.g., by a lickometer circuit) unless EMG electrodes are surgically implanted (see Travers, J. B. *et al.*, 1997). Thus, time and training are required of the experimenter to score videotapes frame by frame.

4.22.3.4 Progressive Ratio Taste Reinforcer Efficacy Test

4.22.3.4.1 Procedure

In the progressive ratio taste reinforcer efficacy test, animals are trained to execute a specific operant response, such as lever pressing or dry-spout licking, to receive a small volume of a taste solution. Initially, the number of responses required to produce the taste reinforcer is low, but the requirement is progressively raised as the session continues until the animal reaches a breakpoint and ceases to respond further (Hodos, W., 1961; Hodos, W. and Kalman, G., 1963; Reilly, S., 1999; Reilly, S. and Trifunovic, R., 1999; Sclafani, A. and Ackroff, K., 2003). The breakpoint is thought to reflect the efficacy of the reinforcer and thus can be construed as a measure of the affective potency of a taste stimulus.

4.22.3.4.2 Strengths

Once trained, deprivation states are unnecessary for normally preferred stimuli (e.g., sucrose), but water deprivation is required to test normally avoided stimuli (e.g., quinine). In the latter case, the motivation to rehydrate is pitted against the aversive characteristics of the taste stimulus. Depending on the step-size schedule, the actual total amount of reinforcer delivered can be kept relatively small, thus attenuating the influence of postingestive factors and satiation. Just as the oromotor taste reactivity test is a pure measure of consummatory/rejection responses, the progressive ratio is a pure measure of appetitive behavior. This is because the behavior, which leads to the presentation of the taste reinforcer, is produced without the stimulus contacting the receptors.

4.22.3.4.3 Limitations

This procedure has the same limitations as some of the other procedures discussed in that the responses are driven by the affective evaluation of the stimulus.

4.22.3.5 Conditioned Taste Aversion

4.22.3.5.1 Procedure

Typically, when ingestion of a specific taste stimulus is followed by injection of a viscerally aversive agent (e.g., lithium chloride (LiCl); see Garcia, J. *et al.*, 1955; Nachman, M. and Ashe, J. H., 1973; Domjan, M., 1980; Barker, L. M. *et al.*, 1999), often after only a single conditioning trial (depending on the dose of the aversive agent), animals will display robust avoidance and rejection behavior in response to the conditioned taste stimulus. Because animals will generalize their conditioned responses to some taste compounds but not others, this procedure has been useful for making inferences about the degree of qualitative similarity between taste stimuli (e.g., Nachman, M., 1963; Tapper, D. N. and Halpern, B. P., 1968; Nowlis, G. H. *et al.*, 1980; Smith, D. V. and Theodore, R. M., 1984).

4.22.3.5.2 Strengths

To the extent that taste aversion generalization paradigms provide information about the sensory-discriminative features of taste solutions, the taste aversion methodology is technically simpler than operant discrimination paradigms. In addition, training is usually effective after a single conditioning trial. If a gustometer is used to measure conditioned avoidance responses, a variety of test compounds can be included in the stimulus array and generalization profiles can be obtained in a single test session.

4.22.3.5.3 Limitations

From a practical perspective, one must be concerned with the possibility of extinction effects that can occur with continued testing that involve the conditioned stimulus or compounds that bear some qualitative similarity to it. This places limits on the number of test sessions and test stimuli that can be included in the design. From a conceptual perspective, conditioned taste aversions are functionally complex measures in that the quality, intensity, hedonics, and even physiological responses (e.g., Berridge, K. *et al.*, 1981) are all potentially involved. These procedures are designed to change the hedonic properties of a specific stimulus identified by its quality. Like all conditioning processes the concentration of the taste stimuli must be considered because generalization can take place along the intensity dimension (Hagstrom, E. C. and Pfaffmann, C., 1959; Tapper, D. N. and Halpern, B. P., 1968; Nowlis, G. H., 1974; Scott, T. R. and Giza, B. K., 1987; Spector, A. C. and Grill, H. J., 1988). Accordingly, a given experimental manipulation of the gustatory system can affect behavioral outcomes in this paradigm by influencing function in one of several of these domains.

Second, it must be remembered that generalization and discrimination, while related, are distinct psychological concepts. For example, taste aversions to sucrose generalize to maltose (e.g., Nissenbaum, J. W. and Sclafani, A., 1987b; Spector, A. C. and Grill, H. J., 1988) and glutamate (Heyer, B. R. *et al.*, 2003), but sucrose can also be discriminated from these compounds on the basis of gustatory cues (Spector, A. C. *et al.*, 1997; Stapleton, J. R. *et al.*, 2002; Heyer, B. R. *et al.*, 2004).

4.22.3.6 Operantly Conditioned Taste Detection and Discrimination

4.22.3.6.1 Procedure

Operantly conditioned taste detection and discrimination tasks have a well-established history of use in the psychophysical examination of a variety of sensory systems in animals (see Blough, D. and Blough, P., 1977; Stebbins, W. C. and Berkley, M. A., 1990). In the study of gustatory processes, generally a taste stimulus is used as a cue for responding in a specific way (see Carr, W. J., 1952; Harriman, A. E. and MacLeod, R. B., 1953; Koh, S. D. and Teitelbaum, P., 1961; Morrison, G. R. and Norrison, W., 1966; Morrison, G. R., 1967; Shaber, G. S. *et al.*, 1970; Slotnick, B. M., 1982; Brosvic, G. M. and Slotnick, B. M., 1986; Spector, A. C. *et al.*, 1990b; Willner, P. *et al.*, 1990; Thaw, A. K. and Smith, J. C., 1992; St. John, S. J. *et al.*, 1997; Stapleton, J. R. *et al.*, 2002; Spector, A. C., 2003). If the response is correctly executed the behavior can be reinforced (e.g., the animal is rewarded); if the response is incorrectly executed, the animal can be punished. For instance, a thirsty rat can be trained to press a left-hand lever if a five-lick stimulus sample is NaCl and a right-hand lever if the sample is water. A correct response can lead to access to 20 licks of water (which is rewarding because the animal is on a water-restriction schedule) and an incorrect response can lead to a 30 s time-out, further delaying the opportunity to receive water. The concentration of the NaCl stimulus can be varied across trials until it reaches a low enough value that the animal does not differentially respond between the taste and water stimulus; thus a detection threshold can be measured. If the water stimulus in the prior example is replaced with a second taste

stimulus (e.g., potassium chloride (KCl)), then the procedure can be used to measure the degree of discriminability between the two taste compounds being tested.

4.22.3.6.2 Strengths

These procedures possess some of the same benefits as the brief-access taste test in that small stimulus samples are used and immediate responses are measured curtailing the influence of postingestive events on responses. In addition, the taste compounds serve as signals for other events (reward or punishment) and, thus, the responses are under the control of the reinforcement contingencies established and not the inherent motivational characteristics of the sapid stimuli.

4.22.3.6.3 Limitations

Under ideal circumstances, the strength of this procedure is that it allows a relatively pure assay of the sensory-discriminative aspects of the tastant. However, animals working for reinforcement may use whatever cues are available. If all of the concentrations of one stimulus are more reinforcing or more aversive than all of the concentrations of the comparison stimulus, then discrimination might arguably take place along a hedonic dimension. For example, if rats were trained to discriminate sucrose from quinine, it is conceivable that such a discrimination could be guided by the hedonic valence of the stimuli as opposed to their qualitative characteristics. In general, because the hedonic potency of a taste stimulus often covaries with its concentration, and several concentrations of each stimulus are presented within a session, there is likely overlap in the affective valence of the discriminated compounds such that the hedonic properties of the stimuli are rendered irrelevant cues. Nevertheless, there may be some stimulus pairs (e.g., sucrose vs. quinine) where hedonically based taste discriminations could be possible.

An additional consideration in the use of discrimination procedures is that it remains possible that animals might use taste cues that are not strictly related to the perceptual quality of the compounds to guide their performance. For example, perhaps compounds evoking similar qualities might vary in their kinetics of reaching or activating receptors such that they differ in the rise and/or decay times of the sensation. Potentially, that information could be used by the animal to competently discriminate between the two stimuli. Although such a possibility remains speculative, it is difficult to entirely dismiss. Because animals potentially have a variety of taste cues not strictly related to the quality of the stimulus per se to guide performance, a failure for an animal to discriminate between two compounds is an interpretively powerful result, provided that learning and motivational factors can be discounted.

4.22.4 Use of Multiple Behavioral Assays Can Provide Rich Insight into the Organization of the Gustatory System

As noted in the introduction, the use of multiple behavioral assays is critical to gain a comprehensive understanding of sensory function; no single behavioral procedure provides a gold standard test. A given assay may reveal taste deficits after a particular experimental manipulation, but other assays may indicate normal function. This is because each behavioral paradigm is influenced by various aspects of taste processing as summarized in Table 1. An experimental manipulation may affect one aspect of taste function (e.g., quality) but not another (e.g., hedonic), and whether performance in a task is affected will depend on the degree to which the behavior in the assay is dependent on the relevant function. Some examples are provided below.

4.22.4.1 Peripheral Mechanisms of Salt Taste

Decades ago, Pfaffmann and Beidler (Pfaffmann, C., 1941; Beidler, L. M., 1953; 1954; Pfaffmann, C., 1955) showed that the chorda tympani (CT) nerve of the rat was exceptionally responsive to sodium salts. Thus, although this nerve innervating the anterior tongue transmits afferent information from a minority of taste buds (in the rat, less than 15% of the total), the electrophysiological data promoted the rational expectation that transection of the CT nerve would severely impair taste sensitivity to salt. Pfaffmann C. (1952) tested this hypothesis by using the two-bottle preference test and comparing salt preference in intact rats, rats with CT nerve transection, and rats with combined transection of both the CT and glossopharyngeal (GL, innervates posterior tongue) nerves (denervating >70% of the total taste buds). To his surprise, none of these transections had an effect on salt preference; an outcome reported by others using similar behavioral paradigms (Richter, C. P., 1939; Akaike, N. *et al.*, 1965; Vance, W. B., 1967;

Grill, H. J. and Schwartz, G. J., 1992; Grill, H. J. *et al.*, 1992). Although some or all of this maintained responsiveness in the neurotomized rats may have been due to the influence of the NaCl on postlaryngeal receptors, a similar lack of effect on salt responsiveness has been observed even when a brief-access taste test, which minimizes the contribution of postingestive events, was used as an assay (Cauthon, R. *et al.*, 1994).

Adulteration of NaCl solutions with the epithelial sodium channel blocker amiloride also has little or no effect on NaCl preference measured in a two-bottle preference test in either C57BL/6 (B6) mice (Figure 1) or F-344 rats (Chappell, J. P. *et al.*, 1998; Eylam, S. and Spector, A. C., 2002). Like the lack of effect of CT nerve transection on NaCl preference, the ineffectiveness of amiloride to alter ingestive behavior in this test was unexpected because the drug notably suppresses CT and greater superficial petrosal (GSP) responses to NaCl in most rodents (e.g., Heck, G. I. *et al.*, 1984; Brand, J. G. *et al.*, 1985; DeSimone, J. A. and Ferrell, F., 1985; Herness, M. S., 1987; Ninomiya, Y. *et al.*, 1989; Hettinger, T. P. and Frank, M. E., 1990; Simon, S. A. *et al.*, 1993; Ye, Q. *et al.*, 1993; Doolin, R. E. and Gilbertson, T. A., 1996; Sollars, S. I. and Hill, D. L., 1998; Lindemann, B. *et al.*, 1999).

One seemingly straightforward conclusion consistent with these behavioral data is that the CT and the epithelial sodium channels in taste receptor cells are not critical in the maintenance of taste sensitivity to NaCl, but such a verdict would be premature. Responsiveness in both the two-bottle preference test and the brief-access taste test are driven by the hedonic characteristics of the stimulus. Moreover, the former procedure is vulnerable to postingestive events and the latter procedure does not have optimal sensitivity in the low concentration range. Neither procedure provides explicit information on the qualitative characteristics of the taste stimulus. Thus, to conclude that rodents had normal salt taste perception following these manipulations in the peripheral gustatory system would be akin to concluding that hamsters are visually normal after visual cortex lesions based on the results of one or only a few behavioral assays.

As it turns out, suppression of the amiloride-sensitive salt transduction pathway or removal of the afferent input from the CT has severe consequences on sodium taste discriminability. When operant conditioning procedures are used to train rats to respond differentially to NaCl and water and the concentration of the stimulus is varied, the resulting detection threshold is shifted 1–2 orders of magnitude by transection of the CT (Spector, A. C. *et al.*, 1990b; Slotnick, B. M. *et al.*, 1991; Kopka, S. L. and Spector, A. C., 2001). When the nerve regenerates, the NaCl detection threshold returns to normal (Kopka, S. L. and Spector, A. C., 2001). Likewise, stimulus adulteration with amiloride, which appears to be tasteless to rats and mice (Markison, S. and Spector, A. C., 1995; Eylam, S. *et al.*, 2003), raises detection thresholds for NaCl and sodium gluconate, but not KCl, measured in operantly trained rats and mice (Geran, L. C. *et al.*, 1999; Geran, L. C. and Spector, A. C., 2000a; 2000b; Eylam, S. and Spector, A. C., 2002; 2003). It is important to note, however, that while CT transection raises the NaCl detection threshold measured in operant conditioning procedures, when a similar task was used to assess NaCl difference thresholds (i.e., just noticeable differences between NaCl concentrations) at mid-range concentrations, CT (or GL) transection had little effect (Colbert, C. L. *et al.*, 2004). Apparently, the input from the remaining gustatory nerves is sufficient in maintaining the ability of rats to make normal intensity discriminations within the NaCl concentration range that is detectable after CT transection.

Thus, amiloride treatment and CT transection decrease the sensitivity of some rodents to NaCl. But do these manipulations have any effect on the qualitative nature of NaCl taste? Rats can be trained to discriminate between salts in operant-conditioning paradigms. In these designs, concentration is varied so that intensity cues are irrelevant. Interestingly, performance of rats in an NaCl versus KCl operant discrimination task is significantly impaired by CT transection, but is unaffected by GL transection (Spector, A. C. and Grill, H. J., 1992; St. John, S. J. *et al.*, 1997; Kopka, S. L. *et al.*, 2000). Combined transection of the CT and GSP, removing all of the taste input of cranial nerve VII, drops performance on either an NaCl versus NH_4Cl or on an NH_4Cl versus KCl taste discrimination task to chance levels, but GL transection is without effect (Geran, L. C. and Spector, A. C., 2002; Geran, L. C. *et al.*, 2002b).

Stimulus adulteration with amiloride also leads to chance performance on a NaCl versus KCl discrimination task in rats and mice (Spector, A. C. *et al.*, 1996a; Eylam, S. and Spector, A. C., 2005). In these experiments, animals had many more errors on NaCl trials than on KCl trials suggesting that when the stimuli are mixed with amiloride, NaCl tastes more similar to KCl than to unadulterated NaCl. In support of this conclusion, taste aversions conditioned to

NaCl mixed with amiloride generalize to nonsodium salts in a brief-access taste test (Hill, D. L. *et al.*, 1990). In contrast, when unadulterated NaCl is used as a conditioned stimulus, rats (and other rodents) will specifically avoid NaCl and LiCl but not nonsodium salts (Nowlis, G. H. *et al.*, 1980; Hill, D. L. *et al.*, 1990; see also Nachman, M., 1963).

Another way in which CT transection and amiloride treatment have been shown to affect the taste quality of NaCl is through procedures that take advantage of the physiological and behavioral mechanisms that apparently evolved to protect herbivores and some omnivores from dangerous deficiencies in body sodium. When rats are acutely depleted of sodium, hormonal mechanisms are engaged that facilitate the reabsorption of sodium and trigger neural circuits that potentiate appetitive and consummatory behavior promoting the search for and ingestion of sodium salts (see Denton, D., 1982; Schulkin, J., 1991). Sodium-depleted rats will display increased intake of NaCl in brief-access, short- and long-term drinking tests (Richter, C. P., 1936; Handal, P. J., 1965; Jalowiec, J. E. and Stricker, E. M., 1970; Wolf, G., 1982; Epstein, A. N., 1984; Bernstein I. L. and Hennessy C. J., 1987; Rowland, N. E. and Fregly, M. J., 1992; Breslin, P. A. *et al.*, 1993a; O'Keefe, G. B. *et al.*, 1994; Brot, M. D. *et al.*, 2000), will enhance their licking response for sodium salts over nonsodium salts in brief-access taste tests (Breslin, P. A. *et al.*, 1993b; 1995; Markison, S. *et al.*, 1995; Geran, L. C. and Spector, A. C., 2004), and will show increased ingestive oral motor consummatory responses to NaCl (Berridge, K. C. *et al.*, 1984; Grill, H. J. and Berridge, K. C., 1985; Grill, H. J. and Bernstein, I. L., 1988). The appetite is specific for salts with a sodium cation; the only exception is lithium which is treated as if it is sodium. Transection of the CT compromises, and amiloride treatment eliminates, the vigor and cation-specificity of depletion-induced sodium appetite in rats (Bernstein I. L. and Hennessy C. J., 1987; McCutcheon, N. B., 1991; Sollars, S. I. and Bernstein, I. L., 1992; Breslin, P. A. *et al.*, 1993b; Sollars, S. I. and Bernstein, I. L., 1994; Breslin, P. A. *et al.*, 1995; Markison, S. *et al.*, 1995; Frankmann, S. P. *et al.*, 1996; Roitman, M. F. and Bernstein, I. L., 1999; Brot, M. D. *et al.*, 2000; Geran, L. C. and Spector, A. C., 2004).

Collectively, the findings from these various behavioral procedures in rats indicate that absolute sensitivity to NaCl, as well as the perceived quality of this salt stimulus, is partially dependent on the input of the CT nerve that likely derives from the activation of the amiloride-sensitive salt transduction pathway. This is consistent with the fact that the rat CT has narrowly tuned fibers that respond to NaCl and LiCl but do not respond well to other salts or acids (Frank, M. E. *et al.*, 1983; Ninomiya, Y. and Funakoshi, M., 1988; Lundy, R. F., Jr. and Contreras, R. J., 1999; Sollars, S. I. and Hill, D. L., 2005). Moreover, the sodium responsiveness of these fibers is significantly suppressed by lingual amiloride treatment (Ninomiya, Y. and Funakoshi, M., 1988). There are, however, other sodium-responsive fibers in the CT and in other gustatory nerves that are not affected by the application of amiloride on their receptor fields (Ninomiya, Y. and Funakoshi, M., 1988; Formaker, B. K. and Hill, D. L., 1991; Kitada, Y. *et al.*, 1998; Sollars, S. I. and Hill, D. L., 2005). It would appear that these amiloride-insensitive fibers are sufficient at providing input that can maintain normal unconditioned avoidance responses to salt. This is presumably one reason why the two-bottle preference test and the brief-access taste test, when used to assess unconditioned responses to NaCl, reveal normal function after CT transection or amiloride treatment. Thus, many of the procedures listed in Table 1 have nicely complemented each other and have collectively provided insight into the principles and peripheral mechanisms associated with salt taste in the rodent model.

4.22.4.2 Use of Behavioral Procedures to Study the Functional Neuroanatomy of the Central Gustatory System

Some of the behavioral procedures in Table 1 have been used to assess taste function after production of experimental lesions in central gustatory structures. Interpretation of the behavioral effects following manipulations of the brain is always challenging because any resulting impairments might have a variety of functional origins. Furthermore, any behavioral deficit following a lesion may not be due to the disruption of processing in the damaged brain site, but might be due to the interruption of information flow to brain regions anatomically downstream. Nevertheless, the complementary use of different behavioral procedures combined with theoretically relevant anatomical manipulations of the brain has offered insight into the functional organization of the central gustatory system in at least the rat model. Some examples are provided below.

4.22.4.2.1 Taste reactivity in decerebrate rats

Gustatory signals from the periphery are transmitted to the rostral one-third of the nucleus of the solitary tract (NST) by branches of cranial nerves VII, IX, and X. In rodents, the main ascending gustatory pathway begins with the projections of the second-order neurons in the NST to third-order taste-responsive neurons in the parabrachial nucleus (PBN). The projections of the third-order neurons in the PBN form two pathways destined for forebrain sites. The first terminates in the parvicellular subdivision of the ventral posteromedial nucleus of the thalamus, which, in turn, projects to the insular cortex. The second pathway terminates in several ventral forebrain regions including the lateral hypothalamus, the central nucleus of the amygdala, and the substantia innominata (see Norgren, R. and Leonard, C. M., 1973; Norgren, R., 1974; 1976; Hamilton, R. B. and Norgren, R., 1984; Halsell, C. B., 1992; Travers, S. P., 1993; Norgren, R., 1995).

About 30 years ago, Grill H. J. and Norgren R. (1978d) made a remarkable discovery that began to shed light on the functional significance of hindbrain and forebrain gustatory circuits. They developed the taste reactivity test procedure (see Section 4.22.3.3) to test the responsiveness of supracollicular decerebrate rats to prototypical taste stimuli (Grill, H. J. and Norgren, R., 1978c). In this neural preparation, the forebrain is neurally isolated from the rest of the nervous system. Animals that survive this procedure do not spontaneously eat and drink and have impairments in body temperature regulation, but they can nonetheless be chronically maintained by gavage feeding and close control of environmental conditions (Grill, H. J. and Norgren, R., 1978b). Despite the fact that these animals are severely compromised behaviorally, they display relatively normal concentration-dependent oral motor responses to taste stimuli (Grill, H. J. and Norgren, R., 1978d). Intraoral infusions of quinine elicit gapes and intraoral infusions of sucrose elicit tongue protrusions and mouth movements. These findings provide convincing evidence that the neural circuits of the caudal brainstem are sufficient to support taste-elicited oral motor reflexes.

In intact rats, taste reactivity can be modified by learning. If the intraoral delivery of a palatable fluid is followed by visceral malaise, animals will display aversive oral motor responses to this normally palatable sugar stimulus when tested on subsequent occasions (e.g., Grill, H. J. and Norgren, R., 1978a; Grill, H. J. and Berridge, K. C., 1985; Spector, A. C. *et al.*, 1988). Grill H. J. and Norgren R. (1978a) went onto show that even though decerebrate rats display relatively normal unconditioned taste reactivity, these animals do not change their response profile even after several pairings of the taste stimulus with a malaise-inducing LiCl injection. Regardless of the functional basis for the impairment, it is clear that the forebrain is necessary for this particular form of taste-related learning to be expressed. The taste reactivity paradigm is the only type of taste-related behavioral measure from Table 1 that can be used in the examination of decerebrate rats. However, its application in the assessment of both unconditioned and conditioned responses to taste stimuli led to fundamental insights concerning the functional significance of caudal brainstem versus forebrain gustatory circuits.

4.22.4.2.2 Taste function after lesions in the gustatory nuclei

One limitation of the decerebration strategy is that it involves a very crude and expansive neural manipulation affecting many different sensory, motor, and autonomic systems. Thus, while functions that survive this substantial neural insult are conceptually meaningful, not much can be said of behaviors that are impaired or eliminated. The interpretative significance of any lesion-induced behavioral deficit depends heavily on the anatomical specificity of the neural manipulation. For close to 50 years, researchers have targeted brain sites along the gustatory pathway and have assessed the degree of behavioral competence following the production of lesions. The early work generally involved large lesions and almost the exclusive use of intake tests to assess taste function (Patton, H. D. *et al.*, 1944; Benjamin, R. M., 1955a; 1955b; Benjamin, R. M. and Akert, K., 1958; Oakley, B. and Pfaffmann, C., 1962; Blomquist, A. J. and Antem, A., 1967; Loullis, C. C. *et al.*, 1978; Braun, J. J. *et al.*, 1982; Hill, D. L. and Almli, C. R., 1983; Lasiter, P. S., 1985; see also, Spector, A. C., 1995a; Reilly, S., 1998). Later investigations involved more anatomically precise lesions often placed with electrophysiological guidance and incorporated more diverse behavioral paradigms (but see Oakley, B. and Pfaffmann, C., 1962; Oakley, B., 1965). Rather than review the entire spectrum of results from such studies, it is worth noting a few findings that highlight the interpretive power of comprehensive behavioral analyses.

The consequences of lesions directed toward the second central relay in the rodent gustatory system, the PBN, provide an interpretive complement to the findings from experiments involving supracollicular transections described in Section 4.22.4.2.1. Overall, a PBN lesion is considerably less drastic than decerebration, but at the same time is anatomically more severe in terms of interrupting gustatory neural circuits. Decerebration presumably leaves intact the NST and PBN as well as connections between these areas and medullary nuclei, including those involved in orofacial motor and physiological reflexes (see Travers, J. B. *et al.*, 1999). Lesions in the gustatory zone of the dorsal pons, in contrast, should limit gustatory processing to the NST and its local connections, to the extent that the PBN is an obligate relay for forebrain taste projections.

From that perspective, it is noteworthy that electrophysiologically guided lesions in the PBN have relatively little effect on the intake of a variety of prototypical taste stimuli by rats (in contrast to the complete suppression of appetitive behavior in the decerebrate). Nonetheless, intake is not normal following this manipulation; investigators have reported overconsumption of several prototypical taste stimuli (e.g., Flynn, F. W. *et al.*, 1991b). Converging evidence for an alteration in taste processing comes from brief-access taste testing (see Section 4.22.3.2). Substantial changes in behavioral responses to quinine, sucrose, and NaCl have been reported in rats with bilateral PBN lesions (Spector, A. C. *et al.*, 1993a; 1995) collectively suggesting that rats are made hypoguesic by this lesion. The simplest explanation is that PBN lesion reduces the perceived intensity of gustatory stimuli, but these data also suggest that hedonic processing and possibly stimulus identification remain intact. For example, although the effective concentration range is shifted to higher concentrations, rats with PBN lesion nonetheless avoid quinine and NaCl in a concentration-dependent manner, and increase licking of sucrose in a concentration-dependent manner.

The simple explanation of hypoguesia (weakened taste intensity) is complicated by another study which demonstrated that detection thresholds measured using operant procedures sometimes were not altered following PBN lesion (Spector, A. C. *et al.*, 1995). That is, individual animals with PBN lesion showed elevated detection thresholds in some cases and not in others. Importantly, all of these animals failed to express a learned taste aversion to either sucrose or NaCl after multiple conditioning trials, a finding that served as functional confirmation of the PBN lesion. Similar individual animal variability has also been reported in operant discrimination procedures; rats with PBN lesion that fail to form conditioned taste aversions are in some cases unable to discriminate NaCl from KCl in an operantly trained discrimination task, but in other cases show near-normal discrimination performance (Spector, A. C., 1995a). Whether the individual differences are related to prelesion training differences, the exact locus and extent of the lesion, or differences in the plasticity of pre-PBN circuitry is unknown. What is clear from this work is that rats with lesions centered in the taste-responsive zone of the dorsal pons are not aguesic, and that their gustatory competence can, in some cases, emulate that of intact rats depending on the task.

Importantly, this residual competence is informative in interpretation of other effects of PBN lesion. As noted, a hallmark of PBN lesion is that, like decerebration, this neural manipulation prevents the formation of conditioned taste aversions (DiLorenzo, P. M., 1988; Ivanova, S. F. and Bures, J., 1990; Flynn, F. W. *et al.*, 1991a; Yamamoto, T. and Fujimoto, Y., 1991; Spector, A. C. *et al.*, 1992; Reilly, S. *et al.*, 1993; Scalera, G. *et al.*, 1995; Spector, A. C. *et al.*, 1995; Grigson, P. S. *et al.*, 1997; 1998; Sclafani, A. *et al.*, 2001) Such a deficit would be expected if PBN lesions rendered the rat aguesic or severely hypoguesic to taste solutions; likewise, rats would not be able to express taste aversions if PBN lesions prevented the identification of a specific taste solution. However, work cited above converges on the conclusion that although some deficits in detection thresholds, suprathreshold sensitivity, and taste discriminability can be seen, those deficits do not always occur and are not severe enough to explain the deficits in taste aversion acquisition. Indeed, if the taste aversion is conditioned presurgically, rats with PBN lesions display normal avoidance of the conditioned taste stimulus, but are unable to learn an aversion to a novel sapid compound (Grigson, P. S. *et al.*, 1997). Clearly, the use of multiple behavioral tests has provided considerable interpretive power in diagnosing the role of the PBN in taste aversion learning and leads to the conclusion that the taste-responsive portion of this nucleus must remain intact for taste signals to be conditionally associated with visceral malaise (see Spector, A. C. *et al.*, 1992; Spector, A. C., 1995a; Norgren, R. and Grigson, P. S., 1996; Grigson, P. S. *et al.*, 1997; 1998).

Likewise, PBN lesions eliminate the expression of a salt appetite (Flynn, F. W. *et al*., 1991a; Scalera, G. *et al*., 1995), impair the formation of a conditioned flavor preference (Sclafani, A. *et al*., 2001), and prevent the avoidance of diets deficient in amino acids or protein (Fromentin, G. *et al*., 2000). Against the backdrop of the behavioral work discussed so far, the interpretation of the cause of these deficits would not rely on the animal failing to taste NaCl, the conditioned stimulus, or the deficient diet. Rather, like with taste aversion, the PBN or its downstream processing targets appear to be indispensable for behaviors that require the integration of taste and viscerosensory signals.

4.22.5 Final Comments

This chapter has provided an overview of the behavioral techniques that have been used to assess taste function in animal, primarily rodent, models. We have attempted to show how these various paradigms can complement each other leading to a more comprehensive interpretation of the effects of experimental manipulations on the gustatory system, be they anatomical, pharmacological, or genetic. Greater coordination in the application of behavioral, neurobiological, and genetic techniques, all of which are evolving rapidly, should ultimately lead to a better understanding of the neural mechanisms underlying taste function and provide a logical bridge potentially connecting findings based on animal models to the study of human gustation.

Glossary

c-Fos protein Product of immediate early gene *c-fos*, regulates the induction of downstream target genes as a transcription factor.

conditioned stimulus (CS) A neutral stimulus which comes to be associated, after training, with an unconditioned stimulus.

emetic Causing nausea and/or vomiting.

latent inhibition A process by which preexposure to a stimulus without consequence retards the learning of subsequent conditioned associations with that stimulus.

N-methyl-D-aspartate (NMDA) receptors One class of glutamate receptors which potentiates synapses in several neural pathways and is believed to be importantly involved in neural plasticity.

phosphorylation The addition of a phosphate to a protein or a small molecule which can switch on or off cellular regulatory events.

protein kinase A cAMP-dependent protein kinase, also known as protein kinase A (PKA), refers to a family of enzymes whose activity is dependent on the level of cyclic AMP (cAMP) in the cell.

unconditioned stimulus (US) A stimulus used in classical conditioning which produces an unconditioned response without any learning.

Flavor cues such as taste, odor, and texture, are critical to food selection. These cues contribute to the palatability of food but they also play a protective role by discouraging the consumption of dangerous edibles. Flavor aversion refers to the avoidance of foods or fluids based on these cues. Aversions can be innate or they can be learned. Innate aversions, as exemplified by bitter avoidance, do not require prior experience, probably evolved to deter consumption of toxic chemicals that could be detected by their taste, and tend to be shared by members of a species. Learned aversions are those that are based on experience, such as consumption of a food prior to a bout of illness or discomfort. In such cases, illness can be a consequence of ingestion or coincidentally associated with it, such as a food eaten just before the onset of a bout of gastroenteritis (stomach flu). Among humans learned aversions tend to be idiosyncratic; that is, individuals differ from one another with respect to the foods that happen to become associated with the malaise.

The topic of this chapter is the sort of aversions which are acquired; those commonly referred to as learned taste aversions. A brief description of the distinctive characteristics of this learning, a review of what is known about the neural mechanisms that underlie it, and a summary of some clinical implications will be provided.

4.23.1 General Description

Animals and humans learn to avoid foods which may have made them sick, and they do this with remarkable facility. This learning is a form of associative conditioning in which an individual comes to avoid a

taste (conditioned stimulus (CS)) which has previously been paired with a treatment that produces transient illness (unconditioned stimulus (US)). Taste aversion learning is unusually robust and has clear adaptive advantages, particularly for omnivorous species which must select from a range of nutrients, some of which may be toxic. However, conditioned taste aversions (CTAs) can also be maladaptive, as in the case where safe, nutritious foods are avoided because of a chance association with symptoms of nausea or malaise. In cases such as gastroenteritis or cancer chemotherapy, the symptoms are not causally related to the food in question but the association and consequent distaste develops anyway (Bernstein, I. L. and Borson, S., 1986).

Several features of taste aversion learning are striking when they are compared to other learning paradigms (Riley, A. L., 2005). CTAs occur rapidly and potently under conditions that could not support other types of learning. Virtually every other conditioning paradigm requires close temporal proximity between presentation of CS and US. CTAs are routinely acquired after delays of several minutes or an hour between exposure to CS taste and US illness (Garcia, J. *et al.*, 1966). When one considers that long delay learning of taste aversions is often displayed after only one conditioning trial, the unusual potency of this learning is quite impressive. The requirement for temporal contiguity, with an optimal range being 500 ms to 2 s is so common a feature of associate learning paradigms that it has been used to build models of the types of cellular signaling processes that might underlie plasticity (Abrams, T. W. and Kandel, E. R., 1988). In this regard taste aversion learning is clearly an anomaly. This raises the question of how neural signaling in CTA circuits bridge a CS–US intervals of minutes and hours (Koh, M. T. *et al.*, 2003). The degree to which similar or unique mechanisms of neural plasticity are recruited and/or modified for this task remains to be determined.

The robustness of food aversion learning is also underscored by the findings of Roll D. L. and Smith J. C. (1972) that rats will acquire aversions even when they are completely anesthetized during and after the time when the US is administered. These findings, replicated and extended by Bermúdez-Rattoni F. *et al.* (1988), imply that these associations can be formed while unconscious.

In the laboratory, taste aversion learning has most often been studied in rats. This is likely to have been a fortuitous choice since rats have proven to be remarkably good at taste aversion learning. This may be due to two characteristics of this species; first, they are omnivores and opportunistic foragers which means that in their natural environment they frequently sample new foods and are thus at risk for encountering toxins. Second, they are unable to vomit which means that once they eat something toxic they cannot dispose of it easily. For these reasons, this species may have been under particularly strong selective pressure to develop a robust and efficient taste aversion conditioning mechanism as a means of toxin avoidance. But rats are certainly not unique in this ability. Taste aversion learning has been demonstrated in an enormous range of animal species, from the very simple, such as the garden slug, *limax* (Sahley, C. L. *et al.*, 1981), to the complex, such as humans (Garb, J. L. and Stunkard, A. J., 1974; Bernstein, I. L., 1978; Logue, A. W. *et al.*, 1981; Midkiff, E. E. and Bernstein, I. L., 1985; Bernstein, I. L. and Borson, S., 1986).

4.23.2 Conditioned Taste Aversion: The Conditioned Stimulus

4.23.2.1 Salience of Taste Cues

Typical CTA training consists of the presentation of a palatable taste solution, such as dilute saccharin, followed by the injection of a nonlethal toxin. In untrained rats saccharin is highly preferred and consumed with enthusiasm. This makes the behavior of the conditioned animals particularly striking, because they avoid the saccharin and appear to actually be disgusted by it.

The earliest characterizations of taste aversion learning emphasized the ease with which taste cues were associated with subsequent illness, and the relative difficulty of associating cues in other sensory modalities (e.g., sounds and sights) with illness (Garcia, J. *et al.*, 1974). This makes sense from an adaptive perspective as foods, and the sensations associated with their ingestion, are the most likely culprits when unpleasant gastrointestinal consequences arise. This left open the question of the salience of other food-related sensations, especially olfaction. When we commonly refer to the flavors of foods and fluids, we conflate taste and odor cues so that taste aversions may actually be flavor aversions, aversions to both the taste and odor of a food. In the laboratory, the contribution of these two modalities can be assessed independently. In rats, odor cues, presented without tastes, are much less effective than taste cues as CSs in aversion conditioning (Palmerino, C. C. *et al.*, 1980). In contrast, if an odor is conditioned in compound with a taste a

phenomenon referred to as taste potentiation of odor is observed. That it, after conditioning the compound (taste plus odor), when the odor is tested in isolation, it is clear that it has become a highly potent cue for avoidance. Under most normal circumstances, then, odors may be important cues in aversion conditioning. Furthermore, it should be noted that reliance on odor cues allows animals to actually avoid ingestion of a toxic or suspicious substance, whereas reliance on taste cues require some sampling and that can be risky.

4.23.2.2 Salience of Novel Tastes

The robust and rapid CTA acquisition which has been described relies heavily on a CS taste characteristic that has not been mentioned yet, that is, the novelty of the taste. Aversions arise extremely rapidly if a CS food or taste is novel, but if an organism has had prior, safe exposure to the food, conditioning is significantly retarded (Revusky, S. H. and Bedarf, E. W., 1967; Garcia, J. *et al.*, 1974) or prevented completely (Koh, M. T. and Bernstein, I. L., 2005). In the laboratory, one or two safe exposures to a taste prior to conditioning can dramatically attenuate learning.

This characteristic of taste aversion learning is dramatic but not unique. An analogous phenomenon has been described in other associative conditioning paradigms and the general process whereby CS preexposure retards conditioning is referred to as latent inhibition (Lubow, R. E., 1973). CTA acquisition shares additional characteristics with other associative learning paradigms. Conditioning strength is positively correlated with CS intensity, US intensity, and number of CS–US pairings. CTAs display generalization and, although very durable, CTAs are subject to extinction (Riley, A. L., 2005).

4.23.3 Conditioned Taste Aversions: The Unconditioned Stimulus

Laboratory studies of taste aversion learning commonly involve administration of a drug, such as lithium chloride (LiCl), as the US. LiCl, and many other US drugs, are known to act as emetics. This might lead one to assume that if a treatment is capable of acting as a US in taste aversion conditioning it probably causes nausea, or at least produces unpleasant symptoms. This is almost certainly not the case. Instead, the CTA literature yields a remarkably varied list of drugs and other treatments which are effective USs in conditioning (Riley, A. L., 2005). Careful examination of these treatments does not reveal particular feature(s) that they have in common (Gamzu, E. *et al.*, 1985). Although emetic drugs are highly effective as USs, many drugs that are not emetic can be effective (Grant, V. L., 1987; Goudie, 1979). Even more puzzling, some effective drugs do not appear to be particularly aversive. A striking demonstration of this is the fact that drugs which humans and animals will self-administer (Hunt, T. and Amit, Z., 1987) can support CTAs. So the claim that taste aversion conditioning can serve as a behavioral assay of aversiveness or toxicity should be met with skepticism.

Although it is clear that nausea is not necessary for the development of food aversions, there is compelling evidence that nausea may play a unique and particularly potent role in this learning. Evidence both from humans and rats (Pelchat, M. L. and Rozin, P., 1982; Pelchat, M. *et al.*, 1983) suggests that the prototypical learned food aversion, where the food becomes genuinely distasteful, generally is associated with symptoms of nausea. One demonstration of this point emerged from a survey undertaken by Pelchat M. L. and Rozin P. (1982) of people who suffered from food allergies. When allergic symptoms included nausea, subjects reported not only that they avoided the food, but that they actually disliked the taste. In contrast, when the allergic response included symptoms such as mouth sores or hives, subjects avoided the food but reported no change in the food's hedonic rating. In other words these subjects avoided eating the food because it would cause unpleasant symptoms, not because they actually found it distasteful. Thus, Pelchat M. L. and Rozin P. (1982) argue that nausea is not only sufficient for the establishment of a taste aversion but is actually necessary for the development of hedonic shifts or distaste toward foods. It is this shift in the hedonic or incentive value of a taste that, some believe, constitutes a genuine learned taste aversion.

4.23.3.1 Neural Mediation of Food Aversion Learning

When humans develop aversions as a result of the coincidental association between consumption of a food and chemotherapy or symptoms of gastroenteritis, the aversions appear to defy cognition. That is, strong aversions arise despite a person's awareness that the target food was not actually the cause of their illness. These findings suggest that food aversion learning is based on relatively primitive associative

mechanisms perhaps involving neural integration occurring in lower brain areas such as the brainstem.

Taste and visceral information converge in the brain stem, within the nucleus of the solitary tract (NTS) although there is little or no overlap between the regions responsive to gustatory and visceral input (Travers, J. B. *et al.*, 1987). Gustatory neurons from the facial, glossopharyngeal, and vagus nerves terminate in the rostral portion of the NTS. The NTS would, therefore, appear to be a critical part of the pathway mediating taste aversion learning. However, Grigson P. S. *et al.* (1997a) found that rats with extensive lesions of the rostral (gustatory) zone of the NTS demonstrated normal taste aversion learning. Since reception of gustatory information would appear to be obligatory to taste aversion learning, one might assume the NTS lesions, though extensive, did not completely eliminate incoming gustatory signals and that a degraded signal is sufficient for the learning.

In contrast to the rather limited role indicated for NTS, the next site in the ascending gustatory and visceral relay, the pontine parabrachial nucleus (PBN), appears to be crucial for taste aversion acquisition. Rats with lesions of the PBN are unable to acquire a CTA (Reilly, S. *et al.*, 1993). This deficit appears to be quite specific. It does not appear to be due to an inability to taste the CS or experience the US but rather to an inability to associate the two stimuli at the time of conditioning. Also, if conditioning occurs prior to lesioning, PBN lesions do not disrupt CTA expression (Grigson, P. S. *et al.*, 1997b). Thus, the PBN appears necessary for taste aversion acquisition but not expression.

Although taste and visceral information converge within the brainstem and pons, these regions do not appear to be sufficient for the integration needed for taste aversion learning. The chronic decerebrate rat has been shown to be incapable of forming the associations necessary for taste aversion learning (Grill, H. J. and Norgren, R., 1978) which suggests that integration of taste and visceral inputs within the brainstem of the rat is insufficient to support the acquisition or expression of taste aversions. A variety of studies indicate that forebrain structures within the ascending gustatory projection are involved in taste aversion learning (Chambers, K. C., 1990; Yamamoto, T. and Fujimoto, Y., 1991). Two regions of particular interest are the amygdala and gustatory (insular) cortex.

Studies examining the effects of amygdala lesions on taste aversion learning have been somewhat inconsistent. Some of the inconsistency may be attributable to differences in lesion method as well as details of the conditioning protocol (Schafe, G. E. *et al.*, 1998; Morris, R. *et al.*, 1999). Overall, a role for the amygdala in CTA acquisition and expression has been supported by lesion studies as well as studies using methods which lack the interpretational limitations of the lesion approach (Schafe, G. E. and Bernstein, I. L., 1996; Koh, M. T. *et al.*, 2003; Koh, M. T. and Bernstein, I. L., 2005). For example, inhibition of immediate early gene expression and protein kinase A signaling within the amygdala has been demonstrated to interfere with CTA acquisition (Lamprecht, R. and Dudai, Y., 1996; Koh, M. T. *et al.*, 2002).

Like the amygdala, the insular cortex (IC) has strong reciprocal connections with NTS and PBN (Saper, C. B., 1982) and lesion studies have been quite consistent in demonstrating attenuation of taste aversion learning after destruction of this area (Lasiter, P. S. and Glanzman, D. L., 1982; 1985; Bermúdez-Rattoni, F. and McGaugh, J. L., 1991). Furthermore, reversible interference with cholinergic function or blockade of *N*-methyl-D-aspartate (NMDA) receptors in rat IC disrupts taste aversion learning (Naor, C. and Dudai, Y., 1996), and protein tyrosine phosphorylation is altered in the IC following training (Rosenblum, K. *et al.*, 1995). Combining IC lesions or inactivation with staining for c-Fos protein also provides evidence for a dynamic role for the IC in CTA learning. Collectively, results support an important role for this region in taste memory and taste aversion learning.

Thus, lesion studies and new molecular techniques, as well as neuroanatomical approaches, have begun to define the pathways involved in processing taste and visceral signals, and in forming the durable associations between them which are the basis of a CTA. The cellular mechanisms which underlie these associations have also begun to be identified. A recent review provides an intriguing theoretical perspective on these processes (Bermúdez-Rattoni, F., 2004).

4.23.4 Food Aversions in Humans

Food aversion learning in humans has been examined principally through the use of survey methods (Garb, J. L. and Stunkard, A. J., 1974; Logue, A. W. *et al.*, 1981; Midkiff, E. E. and Bernstein, I. L., 1985). Characteristics of food aversions reported by humans are generally similar to those observed in laboratory studies of rats. Acquisition often occurs in a single trial, frequently with long delays interposed between tasting the food and experiencing illness. Aversions

were more likely to develop to less familiar as well as less preferred foods. Extinction was reported to be more effective at reducing aversions than forgetting. This raises the question of what role this powerful and primitive learning plays in human food choice.

The extent to which food aversions, learned as a consequence of the association of specific foods with gastrointestinal symptoms, contribute to overall food choice is not simple to determine. Some who have evaluated this issue have concluded that the role of aversion conditioning is minor. They base this on the following reasoning. Many studies have shown that a majority of people surveyed report having experienced the development of a food aversion at some time in their life. However, if the number of people reporting existing food aversions and the number of foods they avoid due to these experiences are calculated, this number is small relative to the large number of foods people seem to dislike which leaves a vast number of food aversions unaccounted for in terms of their cause (Rozin, P. and Vollmecke, T. A., 1986).

Another line of reasoning leads to a different conclusion. There are good reasons to believe that verbal reports of learned food aversions underestimate the actual number of such aversions. Memory researchers distinguish between implicit and explicit memories (Squire, L. R. *et al.*, 1993). Explicit memories are those you are aware of consciously while implicit memories are those you have but are not consciously aware of. Since classical conditioning is more likely to generate implicit than explicit memories, most food aversion learning experiences in humans may form implicit, not explicit, memories. Research indicates that implicit memory formation is less susceptible to anesthesia (Andrade, J., 1995) which might explain the resistance of food aversion learning to anesthesia (Roll, D. L. and Smith, J. C., 1972; Bermúdez-Rattoni, F. *et al.*, 1988). Thus, if all but the most severe learned food aversions form implicit not explicit memories, subjects' recall of taste aversion experiences may not be the most sensitive way to assess aversion conditioning. If this is true then conditioned food aversions may affect food choices and hedonic responses to foods unconsciously and such conditioning may play a significant role in human food choice but this role would be quite difficult to assess methodologically. Also some people who are chronically ill, prone to motion sickness, or otherwise vulnerable to experiencing unpleasant gastrointestinal symptoms may be at a much higher risk of developing these aversions and having them limit their acceptable food choices (Bernstein, I. L. and Borson, S., 1986).

4.23.5 Clinical Implications

As previously noted, learned taste aversions often arise when the consumption of a food or drink is followed by nausea or gastrointestinal malaise. Sometimes the illness is actually caused by the food or beverage consumed, but it is frequently the case that the food and illness are only coincidentally associated. An example of aversions in which there is indeed a causal relationship between CS and US is the common occurrence of aversions to specific alcoholic beverages, such as bourbon or tequila, which were consumed in excess and which led to nausea and vomiting. Aversions to specific alcoholic beverages frequently appear in surveys done with college students, for obvious reasons (Logue, A. W. *et al.*, 1981; Midkiff, E. E. and Bernstein, I. L., 1985). Another situation in which food aversions develop is in patients receiving cancer chemotherapy (Bernstein, I. L., 1978). Drugs used to treat cancer, while frequently effective in halting the growth of tumor cells, can have severe side effects including nausea and vomiting. Cancer patients often develop aversions to specific foods they consume before these treatments, despite their recognition that their chemotherapy and not their lunch was the cause of these symptoms (Bernstein, I. L. and Borson, S., 1986). Recognition that cancer patients are at risk for the development of learned food aversions and that this can affect their appetite and nutritional status has led to interventions which can prevent the development of these aversions (Broberg, D. J. and Bernstein, I. L., 1987).

The rapid acquisition and robustness of learned taste aversions have made them an attractive tool in therapeutic efforts to modify problem behaviors such as alcoholism and smoking. In point of fact, a natural consequence of excessive alcohol consumption is illness, including severe nausea and vomiting. As noted above, these symptoms are effective in inducing aversions to specific alcoholic beverages in many college students. Do alcoholics fail to acquire such aversions? If they acquire such aversions, how do the aversions subsequently affect their drinking? A survey of alcoholics in a treatment facility indicated that alcoholics do acquire taste aversions to alcoholic beverages as a consequence of overconsumption. However, when a taste aversion to a specific alcoholic beverage was acquired, alcoholics avoided that particular beverage, choosing some other alcoholic beverages instead (Logue, A. W. *et al.*, 1983). Chemical aversion therapy involves the use of drugs, such as emetine, to induce nausea and vomiting after alcohol consumption. This

form of therapy has been incorporated into a range of alcoholism treatment packages. Available outcome data from a number of these programs indicate that the effectiveness of their treatment packages in promoting abstinence is quite good. However, the contribution of chemical aversion therapy, *per se*, to the effectiveness of the entire treatment package has not been explicitly evaluated and therefore it remains unknown. Aversion therapy has also been used as an aid to smoking cessation. This involves a rapid smoking procedure which conforms to the taste aversion learning paradigm in that it involves pairing the flavor cues associated with smoking cigarettes with aversive symptoms such as nausea and headache. This procedure has been reported to be effective in producing aversions to the taste and smell of cigarettes and to improve abstinence rates in smoking cessation programs.

Glossary

conditioned taste aversion (CTA) Avoidance and aversion to a substance after an association learning between the ingestion of the substance (CS) and subsequent malaise (US) with gastrointestinal disorders and nausea. Animals remember the taste for a long time and reject its ingestion at subsequent exposures. CTA has unique characteristics such that strong and long-lasting memory can be acquired by a single pairing of the CS and US even with a long (up to several hours) CS–US interval.

When we take a bite of our favorite food, we experience a variety of sensations, and almost simultaneously we will smile and perceive it to be delicious. We will then be motivated to have more bites, the jaws and tongue move rhythmically with salivary secretion and active gastrointestinal functions to ingest the food. Eventually, the ingestive behavior finishes with the satisfaction of feeling full. Sometimes if something is palatable, we will overeat. Some of our favorite foods may have been innately determined, e.g., cakes and chocolates with innately preferred sweet tastes, but others are acquired after good experiences, or as a more specific example, on the basis of association learning between taste perception and nutritive postingestional effects. Conversely, even favorite foods can become aversive and avoided as a consequence of an unpleasant experience including postingestional malaise. Such taste-mediated behaviors can be commonly observed in everyone. In this chapter, we review the literature regarding these different aspects of pleasantness and rewarding eating behavior and discuss the underlying anatomy, neural substrates, and chemical mediators in the brain, learning and memory processes, and finally the activation patterns in the human brain.

4.24.1 Central Pathways Involved in Hedonic Evaluation

4.24.1.1 Inputs from the Gustatory Pathway to Reward System and Feeding Center

Central gustatory pathways have been well studied and documented in monkeys (Rolls, E. T., 2004) and rodents, especially rats (Norgren, R., 1995). Figure 1 shows a schematic diagram of some of the gustatory pathways in rats. Branches of the facial, glossopharyngeal, and vagus nerves, which synapse with receptor cells in the taste buds, convey taste messages to the first relay nucleus, the rostral part of the nucleus tractus solitarius (NTS). The second relay nucleus for ascending taste inputs is the parabrachial nucleus (PBN) of the pons. The third relay nucleus is the medial parvocellular component of the ventrobasal complex of the thalamus (VPMpc). This thalamic nucleus projects to the gustatory cortex (GC), the cortical gustatory area in the insular cortex (IC). Other ascending projections from the PBN are to the lateral hypothalamus (LH) (not shown in Figure 1), the central nucleus of the amygdala, and the bed nucleus of the stria terminalis (not shown in Figure 1). In monkeys, however, ascending fibers of neurons in the gustatory area of the NTS directly reach the VPMpc, bypassing the PBN (Beckstead, R. M. *et al.*, 1980). It is known that general visceral inputs also project in a similar fashion to the brain regions in parallel with the gustatory projections described above.

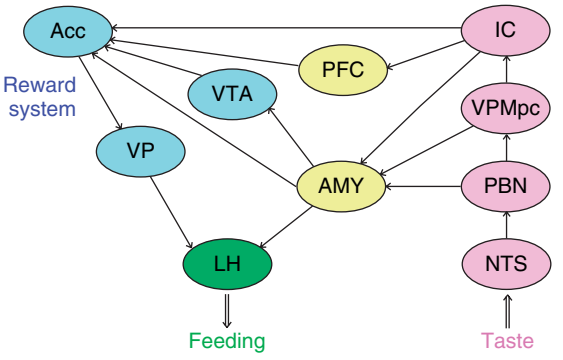

Figure 1 Diagram of connections from the taste system to reward system and feeding center. NTS, nucleus of tractus solitarius; PBN, parabrachial nucleus; VPMpc, parvocellular part of the ventralis posteromedial thalamic nucleus; IC, insular cortex; PFC, prefrontal cortex; AMY, amygdala; VTA, ventral tegmental area; Acc, nucleus of accumbens; VP, ventral pallidum; LH, lateral hypothalamic area. Note that this diagram does not include all of the connections.

The neural pathway of the brain reward system has also been studied and documented (Berridge, K. C. and Robinson, T. E., 1998; Wise, R. A., 2002 for reviews). As shown in Figure 1 and described in more detail in the following sections in this chapter, the essential components are the ventral tegmental area (VTA) in the midbrain, the origin of the mesolimbic dopamine system, the nucleus accumbens (Acc), an essential interface between motivation (e.g., palatability) and action (e.g., feeding), and the ventral pallidum (VP) situated between the Acc and LH, known as the feeding center.

When we consider the roles of taste in feeding and reward, we have to make clear how the taste system interacts with the reward and feeding systems. However, this has not yet been well clarified. The amygdala (AMY), the prefrontal cortex (PFC) including the ventrolateral (or anterior sulcal) and dorsomedial cortices, and IC are the candidates for the interfaces between the two systems. The gustatory insular cortex sends axons to the PFC (Saper, C. B., 1982; Shi, C.-J. and Cassell, M. D., 1998), and the dorsomedial PFC neurons actually respond to gustatory stimuli (Lukáts, B. *et al.*, 2002; Karádi, Z. *et al.*, 2005). Among other structures, the PFC is interconnected with the feeding-related subcortical areas such as the basal forebrain (Divac, I. *et al.*, 1978), amygdala (Pérez-Jaranay, J. M. and Vives, F., 1991), LH (Kita, H. and Oomura, Y., 1981), VTA (Divac, I. *et al.*, 1978; Kosobud, A. E. *et al.*, 1994), and Acc (Brog, J. S. *et al.*, 1993). Behavioral studies have shown that the PFC is associated with various mechanisms in the central control of feeding, for example, lesions of the dorsomedial PFC result in finickiness (Kolb, B. and Nonneman, A. J., 1975) and impairment of conditioned taste aversion (CTA) (Hernádi, I. *et al.*, 2000; Karádi, Z. *et al.*, 2005), while lesion and electrical stimulation of the ventrolateral PFC induce feeding disturbances (Kolb, B. and Nonneman, A. J., 1975; Brandes, J. S. and Johnson, A. K., 1978) and feeding (Bielajew, C. and Trzcinska, M., 1994), respectively.

4.24.1.2 Central Representation of Flavor

It is widely accepted that flavor is the integrated sensation of taste and odor, and often the somatic sensations of texture and temperature are included (Bartoshuk, L. M. and Beauchamp, G. K., 1994 for a review). Flavor contributes significantly to hedonic evaluation of food and feeding behavior. The brain sites involved in flavor evaluation are thought to be the regions where taste and other sensory inputs are

integrated. In rodents, although neurons in the NTS, PBN, and VPMpc are more or less responsive to taste, tactile, and thermal stimulation of the tongue, more intense overlapping activation including olfactory and visceral inputs are in regions of the GC (Shipley, M. T. and Geinisman, Y., 1984; Yamamoto, T. *et al*., 1989a), amygdala (Azuma, S. *et al*., 1984; Nishijo, H. *et al*., 1998c), and hypothalamus (Yamamoto, T. *et al*., 1989b). In monkeys, single-neuron recording studies have identified neurons responsive to both taste and smell in the insula/operculum, the primary GC (Scott, T. R. and Plata-Salaman, C. R., 1999 for a review), and orbitofrontal cortex (Rolls, E. T. and Baylis, L. L., 1994). Some neurons in the monkey orbitofrontal cortex receive visual (Rolls, E. T. and Baylis, L. L., 1994) and somatosensory inputs related to fat-like texture (Rolls, E. T. *et al*., 1999) and viscosity of the texture (Rolls, E. T. *et al*., 2003) in the mouth. Neurons in the amygdala also respond to different sensory inputs (Nishijo, H., *et al*., 1988a; 1988b). In a recent neuroimaging study in humans, Small D. M. *et al*. (2004) suggest that the insula, orbitofrontal cortex, and anterior cingulate cortex are key components of the network underlying flavor perception and that taste–smell integration is dependent on the mode of olfactory delivery, the orthonasal or retronasal routes, and previous experience with taste and smell combinations.

4.24.1.3 Taste-Mediated Reflexes

Taste stimuli evoke a variety of autonomic and hormonal reflex responses including salivary secretion, increases in gastric motility and gastric acid, exocrine pancreatic secretion, and endocrine secretions (Pavlov, I. P., 1902; Janowitz, H. D. *et al*., 1950; Novis, B. H. *et al*., 1971; Fischer, U. *et al*., 1972; Steffens, A. B., 1976; Nicolaidis, S., 1977; Ohara, I. *et al*., 1988; Niijima, A., 1991; Ohara, I. *et al*., 1996). In addition to these responses, taste stimuli elicit somatic motor responses involving mainly lingual and oral-facial muscles (Steiner, J. E., 1973; Grill, H. J. and Norgren, R. 1978a). Cephalic phase insulin release is a reflexly induced secretion elicited by oral stimulation with taste stimuli especially including sweet- (Steffens, A. B., 1976; Berthoud, H. R. *et al*., 1980) and umami-tasting (Niijima, A. *et al*., 1990) substances. Such a taste quality-specific reflex can also be seen for salivary secretion, as shown below.

4.24.1.4 Salivary Secretion

Salivary secretion occurs when sapid foods are put in the mouth, termed the gustatory-salivary reflex. The volume and chemical composition of saliva reflexly induced by taste stimulation are markedly different depending on the quality (Baxter, H., 1933; Kerr, A. C., 1961; Newbrun, E., 1962; Funakoshi, M. and Kawamura, Y., 1967; Gantt, W. H., 1973) and nature of the gustatory stimulus. Dry bread induces a copious serous saliva and meat elicits a small amount of mucous saliva (Pavlov, I. P., 1902). Gjorstrup P. (1980) found that sweet stimuli regularly produced a large increase in the amylase secretion from the parotid gland of conscious rabbits, salty stimuli had a small effect, and sour and bitter stimuli had a negligibly small effect.

It is generally known that the most copious salivary secretion is induced by sour (or acid) stimulation (Kerr, A. C., 1961; Emmelin, N. and Holmberg, J., 1967; Funakoshi, M. and Kawamura, Y., 1967) and that the amount of secretion increases with the stimulus concentration (Feller, R. P. *et al*., 1965; Chauncey, H. H. and Feller, R. P., 1967). The gustatory-salivary reflex has been studied in anesthetized decerebrate animals (Yamamoto, T. and Kawamura, Y., 1977; Kawamura, Y. and Yamamoto, T., 1978; Matsuo, R. and Yamamoto, Y., 1989; Matsuo, R. *et al*., 1989; 2001) where taste neurons in the lower brainstem (NTS and/or PBN) and the salivatory nuclei are involved. These studies have shown that the magnitude of response of the gustatory afferent neurons to taste stimulation is correlated with the volume of salivary secretion regardless of the taste quality, except for copious secretions to strong acids (Kawamura, Y. and Yamamoto, T., 1978) and bitter tastes accompanying rejection behaviors (Matsuo, R. *et al*., 2001). According to Matsuo R. *et al*. (2001), aversive taste information from the PBN reaches the salivatory secretory center via the reticular formation ventral to the PBN with a slight contribution of the connection between the NTS and the salivatory nuclei.

Since the amount of salivary secretion elicited by taste stimulation is markedly reduced after lesions of the cortical taste area in conscious dogs (Funakoshi, M. *et al*., 1972), higher central nervous system structures may also be involved in the modulation of activity of the reflex arc in conscious animals.

4.24.1.5 Somatic Motor Responses

Animals as well as humans accept and ingest sweet and slightly salty substances (e.g., sucrose and NaCl),

while they reject very sour and bitter substances (e.g., HCl and quinine), accompanied by particular oral-facial movements. The possibility that such acceptance or rejection behaviors based on the hedonics of taste are determined in the brainstem without higher cortical involvement was first noticed by Miller F. R. and Sherrington C. R. (1916).

Effects of taste stimuli on tongue motility have been reported in human neonates. For example, Weiffenbach J. M. and Thach B. T. (1973) reported that a drop of glucose solution, but not water, to the tongue elicited lateral tongue movement toward the site of the sapid stimulation. Nowlis G. H. (1973) has pointed out that human newborn infants are capable of eliciting differential tongue movements depending on the quality of gustatory stimuli. Moreover, Steiner J. E. (1973) observed that human newborn infants showed active and differential oral-facial expression based on the hedonic dimension of gustatory stimuli. The responses to sugar (sweet taste) and quinine (bitter taste) were characterized by expressions of pleasure (or relaxation and acceptance) and displeasure (or rejection), respectively. He concluded that the neural substrate of such hedonic behavior is located at the brainstem level, because essentially identical features of facial expression were observed in anencephalic and hydroanencephalic neonates.

Taste-elicited behavioral displays were also investigated in rats (Grill, H. J. and Norgren, R., 1978a; 1978b) and newborn rabbit pups (Ganchrow, J. R. *et al.*, 1979). Grill H. J. and Norgren R. (1978a) analyzed the pattern of tongue, jaw, and body movements in normal and decerebrate rats in response to an injection of a small amount of taste solution into the oral cavity and showed that sucrose, NaCl, and HCl solutions elicited a response sequence beginning with rhythmic mouth movements followed by rhythmic tongue protrusions and then lateral tongue movements, while quinine induced a response beginning with gaping followed by various characteristic body responses. These behavioral experiments on animals again show that taste-elicited behaviors can be grouped into acceptance and rejection based on hedonics of tastes, and these behaviors depend only on the lower brainstem.

When taste solutions were infused into the mouth, c-*fos* was strongly expressed in the lateral and intermediate zones of the medullary reticular formation, which includes premotor neurons of masticatory, facial and tongue motor systems (DiNardo, L. A. and Travers, J. B., 1994; Travers, J. B. *et al.*, 1999). This area receives inputs from the taste areas of the NTS (Shammah-Lagnado, S. J. *et al.*, 1992; Halsell, C. B. *et al.*, 1996) and PBN (Herbert, H. *et al.*, 1990; Karimnamazi, H. and Travers, J. B., 1998). These findings suggest that taste information reaches the motor nuclei through the medullary reticular formation to generate well-organized taste-elicited motor reactions.

4.24.2 Substances Related to Palatability

This section describes several neurochemicals that appear to be related to taste hedonics, especially to palatability. We discuss the possible involvement of dopamine with palatability in the next section.

4.24.2.1 Benzodiazepine

Benzodiazepines such as chlordiazepoxide and diazepam are widely prescribed for the treatment of anxiety disorders. A considerable body of evidence has indicated that benzodiazepine agonists, which facilitate the opening of Cl^- channels in response to $GABA_A$ receptor activation, promote food intake (Berridge, K. C. and Peciña, S., 1995 for a review). Although in most studies, this hyperphagic effect has been shown in rodents, benzodiazepines also enhances food intake in rhesus monkeys (Foltin, R. W. *et al.*, 1985), baboons (Foltin, R. W. *et al.*, 1989), and humans (Haney, M. *et al.*, 1997).

Because of their well-known anxiolytic and sedative actions, the facilitatory effect of benzodiazepines on food intake was once interpreted as an indirect consequence (Poschel, B. P. H., 1971). However, the following results suggest that benzodiazepine-induced hyperphagia is not due to secondary effects of benzodiazepine on anxiety or arousal. First, benzodiazepine agonists increase food intake in rats under nonstressful conditions of the home cage (McLaughlin, C. L. and Baile, C. A., 1979; Cole, S. O., 1983). Second, while sedative effects are rapidly reduced by repeated treatments with benzodiazepine, tolerance to the hyperphagic effects slowly develops (Wise, R. A. and Dawson, V., 1974). Third, while some partial agonists of benzodiazepine (Ro16-6028, Ro17-1812, Ro23-0364) facilitate food intake, these drugs do not produce a strong sedative effect (Cooper, S. J. and Green, A. E., 1993). Other types of benzodiazepines (CGS 9895 and CGS 9896) diminish behavioral expressions of anxiety and arousal

without facilitating food intake (Cooper, S. J. and Yerbury, R. E., 1986). Thus, the benzodiazepine neural systems that modulate anxiety are thought to be separable from those that increase feeding.

In earlier studies, the hyperphagic effect of benzodiazepines was considered to be due to an antisatiety effect (Margules, D. L. and Stein, L., 1967) or to a hunger-inducing effect (Wise, R. A. and Dawson, V., 1974). Several lines of evidence, however, strongly suggest that benzodiazepines specifically enhance the hedonic palatability of food (Cooper, S. J. and Estall, L. B., 1985; Berridge, K. C. and Peciña, S., 1995). For example, systemic administration of benzodiazepines selectively increase the intake of preferred foods such as cookies, sweetened foods, and saccharin solution, but not the intake of regular chow or plain water (Cooper, S. J. and McClelland, A., 1980; Cooper, S. J., 1987; Cooper, S. J. and Yerbury, R. E., 1988; Parker, L. A., 1991).

Since these studies used the volume (g or ml) of food or fluid consumed as a measure for pharmacological modulation of feeding, some factors other than intraoral taste stimulation might have affected the results. Cooper S. J. *et al.* (1988) reported that a benzodiazepine agonist facilitated, and an antagonist reduced, sucrose sham feeding in the gastric-fistulated rat, suggesting that benzodiazepine-induced hyperphagia is not due to postingestional factors.

Although the hedonic aspect of the taste of food and fluid is one of the most important factors that affect feeding, it is difficult to determine the perceived palatability in animals from the volume of food or fluid consumed. Grill H. J. and Norgren R. (1978a) developed a more direct method to quantify palatability (termed taste reactivity), which measures a characteristic set of orofacial and somatic responses that rats display when taste solutions are infused directly into their mouths. For example, sucrose solution elicits an ingestive taste reactivity pattern of tongue protrusions, paw licking, and mouth movements, while bitter quinine solution elicits an aversive taste reactivity pattern such as gaping, chin rubbing, and paw pushing. Mildly aversive taste solutions elicit predominantly passive drips. Using the taste reactivity test, Berridge K. C. and Treit D. (1986) have showed that systemic injection of chlordiazepoxide, a benzodiazepine agonist, selectively facilitates positive hedonic responses to sucrose infusions into the mouth. In contrast, chlordiazepoxide has little or no effect on aversive reactions elicited by quinine. Since such a selective enhancement of hedonic reactivity patterns by benzodiazepine agonists is blocked by benzodiazepine antagonist Ro 15-1788 (Treit, D. *et al.*, 1987), the effects of benzodiazepines on taste palatability are benzodiazepine receptor specific. Similar enhancements of positive palatability to taste stimuli induced by benzodiazepines have been reported by several studies using the taste reactivity test (Gray, R. W. and Cooper, S. J., 1995; Söderpalm, A. H. and Hansen, S., 1998). In addition to taste reactivity, Higgs S. and Cooper S. J. (1997; 1998a) showed that benzodiazepines increased bouts of licking for highly palatable solutions by a microstructural analysis of licking behavior in a brief contact test in the rat.

Aside from these behavioral and pharmacological evaluations, it is important to identify the site(s) in the central nervous system on which benzodiazepines act to enhance palatability. The distribution of benzodiazepine receptors is relatively greater in the forebrain than in the lower brainstem (Richards, J. G. and Mohler, H., 1984). Nevertheless, recent evidence strongly suggests that benzodiazepines act on the particular receptors in the lower brainstem and enhance taste palatability. In an attempt to determine a possible site of benzodiazepine action, Berridge K. C. (1988) examined taste reactivity in chronic decerebrate rats that are known to demonstrate normal affective taste reactivity (Grill, H. J. and Norgren, R., 1978b). Systemic benzodiazepine injection facilitated the positive taste reactivity in response to normally preferred taste solutions, indicating that the midbrain and/or hindbrain seem to contain the minimum benzodiazepine receptors and neural circuitry required to enhance positive hedonic reactions to taste. The notion is supported by the result that in normal rats, benzodiazepine is more effective at eliciting feeding (Higgs, S. and Cooper, S. J., 1996a) and enhancing positive hedonic reactions to oral sucrose (Peciña, S. and Berridge, K. C., 1996) when microinjections are made in the fourth ventricle (lower brainstem) than in the lateral ventricle (forebrain). Furthermore, direct administration of the benzodiazepine agonist midazolam into the PBN increases the consumption of palatable food (Higgs, S. and Cooper, S. J., 1996b) and positive taste reactivity (Söderpalm, A. H. and Berridge, K. C., 2000), suggesting that the PBN is the most probable region on which benzodiazepines act to influence food intake. Because the PBN is the second gustatory relay, it is likely that benzodiazepines act on specific receptors in the PBN to modify taste information so as to enhance taste palatability and facilitate consumption of food.

Some results suggest that the enhancement of palatability induced by intra-PBN injection of benzodiazepine is mediated by $GABA_A$ receptors in the PBN. It is well known that benzodiazepines act on the $GABA_A$ receptor to increase its affinity for GABA. In fact, GABA functions as an inhibitory neurotransmitter in both gustatory and visceral part of the PBN, mediated in part, by $GABA_A$ receptors (Kobashi, M. and Bradley, R. M., 1998). Shimura T. *et al.* (2004) found that systemic injection of midazolam increased the intake of a sucrose solution in wildtype mice but not in mice deficient in the 65-kDa isoform of glutamate decarboxylase (GAD65), a GABA synthetic enzyme in the central nervous system. The results indirectly suggest that GAD65-generated GABA is necessary for benzodiazepines to enhance taste palatability in the PBN. Nevertheless, greater understanding of the physiological significance of benzodiazepines for taste palatability awaits further investigation.

4.24.2.2 Opioids

Various endogenous opioids and their receptor subtypes are found in diverse brain regions, particularly within sites involved in emotion, pain and stress, and endocrine function and feeding (Mansour, A. *et al.*, 1987). Long before the discovery of endogenous opioids, it had been demonstrated that systemic morphine administrations increase food intake in rats (Flowers, S. H. *et al.*, 1929; Martin, W. R. *et al.*, 1963). Since the demonstrations that opioid antagonists reduce food intake at appropriate dosages (Holtzman, S. G., 1974; Brown, D. R. and Holtzman, S. G., 1979), many studies have examined the involvement of opioids in the regulation of food intake (Glass, M. J. *et al.*, 1999 for a review). In general, opioid agonists facilitate and antagonists diminish food consumption. Although precise mechanisms are still unclear, evidence supports the hypothesis that opioids modulate food and taste palatability, leading to increased food intake (Cooper, S. J. and Kirkham, T. C., 1993 for a review). One reason for this hypothesis is that the hyperphagic effect is selective to normally preferred food and tastes. For example, the preference for sweet solutions over water is abolished by systemic administration of opioid antagonist naloxone in rats (Le Magnen, J. *et al.*, 1980). Naltrexone, an opioid antagonist, does not modify the energy intake in control rats receiving ordinary chow but suppresses hyperphagia induced by a highly palatable diet (Apfelbaum, M. and Mandenoff, A., 1981). Both naloxone and naltrexone abolish the preference for a highly palatable saccharin solution in water-deprived rats due to a selective decrease in the consumption of the saccharin solution, with no effect on water intake (Cooper, S. J., 1983).

Studies with the taste reactivity test show that systemic morphine administrations selectively increase positive hedonic reactions to a mixture of sucrose and quinine solution without enhancing aversive reactions (Doyle, T. G. *et al.*, 1993), suggesting that opioid-induced feeding is at least partly mediated by increased palatability of food. Since opioid receptor antagonists reduce sucrose sham feeding in the gastric-fistulated rat (Kirkham, T. C. and Cooper, S. J., 1988), intraoral but not postingestional factors seem to affect opioid-induced modification of feeding. In addition, using a microstructural analysis of licking pattern for sucrose or fat emulsion, Higgs S. and Cooper S. J. (1998b) showed that palatability is modulated by opioids.

In fact, blood levels of β-endorphin levels increase after the consumption of palatable sweeteners and decrease following the intake of aversive quinine in thirsty rats (Yamamoto, T. *et al.*, 2000). β-Endorphin levels in the cerebrospinal fluid, on the other hand, increase after water consumption by thirsty rats. The difference in β-endorphin levels between blood and cerebrospinal fluid suggests that two opiate systems separately function during the intake of fluid.

Experimental work in humans also supports the notion that the modification of feeding produced by opioid agonists and antagonists is mediated by a hedonic shift in the palatability of food and fluid. Fantino M. *et al.* (1986) showed that naltrexone produces a significant decrease on a subjective pleasure scale for sweetened solution in normal human subjects. Naloxone reduces taste preferences for sweet high-fat foods such as cookies or chocolate in both binge eaters and controls (Drewnowski, A. *et al.*, 1992).

Intracerebroventricular as well as systemic administration of opioid agonists facilitates food intake (Gosnell, B. A., 1987). Moreover, the opioid antagonist naloxone causes a reduction in food intake when injected intracerebroventricularly at a dose that is ineffective when administered peripherally (Gosnell, B. A., 1987). Morphine administrations into the lateral ventricle increase both positive hedonic taste reactivity patterns and feeding (Peciña, S. and Berridge, K. C., 1995). These results favor the notion that opioids act centrally to modify food intake.

Although opioids are believed to affect multiple feeding systems (Glass, M. J. *et al.*, 1999), recent evidence strongly suggests that the nucleus accumbens and its associated circuitry are primarily involved in palatability-dependent feeding (Kelley, A. E. *et al.*, 2002 for a review). We describe several lines of evidence that support this hypothesis in the next section.

The hypothalamus is known to be an important region of opioid action for food intake. Microinjections of β-endorphin into the ventromedial nucleus (Grandison, L. and Guidotti, A., 1977) or the paraventricular nucleus (McLean, S. and Hoebel, B. G., 1983) of the hypothalamus facilitates food intake in satiated rats. On the contrary, localized injections of naloxone into the paraventricular nucleus of the hypothalamus significantly reduces food intake (Woods, J. S. and Leibowitz, A. F., 1985). However, these studies suggest that opioids in the hypothalamus are involved in energy needs rather than the palatability of food.

The gustatory relays in the lower brainstem also appear to be sites on which opioids act to facilitate feeding. Infusion of the selective mu-opioid receptor agonist [d-Ala2,N-Me-Phe4,Gly5-ol]enkephalin (DAMGO) into the lateral PBN increases food intake and naloxone antagonizes DAMGO-induced feeding (Wilson, J. D. *et al.*, 2003) Injection of DAMGO into the NTS, the first gustatory relay, stimulates food intake, whereas injection of either the delta or kappa receptor agonist has no effect (Kotz, C. M. *et al.*, 1997). Microinfusion of methionine-enkephalin into the NTS suppresses both spontaneous and evoked activity of more than 20% of taste responsive neurons (Li, C. S. *et al.*, 2003). These effects are blockable by naltrexone, which alone is without effect, suggesting that opioids play some role in processing of taste information in the NTS.

4.24.2.3 Cannabinoid

Recent evidence suggests that the endocannabinoid system is involved in the control of food intake mainly by modulating food and taste palatability (Cooper, S. J., 2004 for a review). The psychoactive effects of marijuana are largely attributable to a constituent called THC (delta-9-tetrahydrocannabinol). Various cannabinoids which are chemicals of the same class as THC may also be psychoactive (Kephalas, T. A. *et al.*, 1976). Since the discovery of a specific receptor in the brain for cannabinoids and endogenous ligands (Devane, W. A. *et al.*, 1992), increasing attention has been directed to possible behavioral functions of endocannabinoids, including a role in feeding. Although earlier studies had suggested that marijuana facilitates appetite and food intake in humans (Abel, E. L., 1971; Foltin, R. W. *et al.*, 1986), a hyperphagic effect had not been demonstrated clearly in animal studies until recently. Several recent studies have shown that endocannabinoids can facilitate food intake under certain conditions. For example, both the exogenous cannabinoid THC and the endocannabinoid arachidonoyl ethanolamide (anandamide) stimulate eating in presatiated rats, with a marked reduction in latency to feed (Williams, C. M. and Kirkham, T. C., 2002). Microstructural analyses of licking reveal that THC and anandamide significantly increase both the total number of licks and bout duration (Higgs, S. *et al.*, 2003). These results suggest that cannabinoids promote eating by increasing the incentive value of food.

Microinjection of 2-arachidonoyl glycerol (2-AG) into the nucleus accumbens shell robustly increases food intake (Kirkham, T. C. *et al.*, 2002). Since subcutaneous administration of a cannabinoid receptor antagonist blocked the hyperphagic response, cannabinoids in the nucleus accumbens appear to be involved in the facilitation of food intake. Microinjection of the cannabinoid receptor agonist CP55,940 into the fourth, but not lateral, ventricle increases consumption of highly palatable sweetened condensed milk (Miller, C. C. *et al.*, 2004), suggesting that cannabinoids can act on the hindbrain to enhance food intake. Nevertheless, our knowledge about behavioral mechanisms of cannabinoid-induced hyperphagia is still quite limited. Further studies are needed to conclude that endogenous cannabinoids directly affect palatability leading to food intake.

4.24.2.4 Substances Related to Negative Hedonics

While studies of substances related to negative hedonics of taste are quite limited, Yamamoto T. *et al.* (1990) showed that the calcitonin gene-related peptide (CGRP)-like immunoreactivity levels in the gustatory insular cortex were increased by aversive taste stimuli such as quinine and even by palatable stimuli such as NaCl and sucrose, if animals had been trained to avoid them by conditioning. The results suggest that CGRP in the GC is implicated in rejection or avoidance behaviors to aversive taste stimuli.

Recent evidence suggests that diazepam-binding inhibitor (DBI), the only known endogenous ligand of the benzodiazepine receptor, is related to negative hedonics of taste. DBI-like peptide is released by aversive quinine stimuli (Manabe, Y. *et al.*, 2000). Injection of a DBI fragment into the fourth ventricle suppressed the intake of 5% sucrose solution and water and increased the aversive taste reactivity to NaCl in mice (Manabe, Y. *et al.*, 2001). In contrast with the facilitatory effect of exogenous benzodiazepine agonists for positive palatability, the possible role of the endogenous DBI for negative hedonics is of interest.

Histamine, which is widely distributed in the mammalian central nervous system as a neurotransmitter or neuromodulator, also seems to be related to negative hedonics of taste. Intraoral infusions of quinine-HCl increase hypothalamic histamine release, but infusions of sucrose or saccharin produced a decrease in histamine levels, suggesting that histamine plays a role in the behavioral expression to aversive taste stimuli (Treesukosol, Y. *et al.*, 2005).

4.24.3 Role of the Reward System in Taste-Mediated Behavior

4.24.3.1 What is the Reward System?

Rats (Olds, J. and Milner, P. M., 1954), humans (Bishop, M. P. *et al.*, 1963), and many other species will perform a response, such as pressing a lever, in order to obtain direct electrical stimulation to specific sites in their own brains. Originally, Olds and Milner argued that the specific brain sites that mediate self-stimulation are those that normally mediate the pleasurable effects of natural rewards (e.g., food, water, and sex). Although there have been numerous debates for a relatively long period, the current consensus seems to be that the circuits mediating intracranial self-stimulation phenomena are reward circuits. Similarly, it is well documented that the brain reward systems are neural substrates for the rewarding effects of addictive drugs. The mesolimbic dopamine system, arising from dopaminergic neurons in the VTA of the midbrain to terminate in the nucleus accumbens, has been shown to play a particularly important role in natural as well as drug rewards (Wise, R. A., 2002 for a review).

Many studies have shown that activation of dopamine systems is triggered in animals by encounters with food, sex, drugs of abuse, and intracranial self-stimulation (Berridge, K. C. and Robinson, T. E., 1998 for a review). In humans, a functional MRI study also reported that presentation of rewards such as cocaine to cocaine-dependent subjects modulated activity in dopamine target sites including the nucleus accumbens (Breiter, H. C. *et al.*, 1997).

4.24.3.2 The Role of Dopamine in Food Reward

It is well known that dopamine affects feeding behavior (Blackburn, J. R. *et al.*, 1992 for a review). Systemic administration of pimozide, a dopamine receptor antagonist, attenuates lever pressing and running for food reward in hungry rats (Wise, R. A. *et al.*, 1978). Pimozide also suppresses the consumption of a saccharin-glucose solution in a dose-related manner (Xenakis, S. and Sclafani, A., 1981; Geary, N. and Smith, G. P., 1985). These early studies favor the view that dopamine receptor blockade reduces the rewarding impact of palatable stimuli, including food (Wise, R. A., 1982). However, taste reactivity analyses have shown that dopamine is less likely involved in modifying palatability. Berridge and his colleagues (Berridge, K. C. *et al.*, 1989; Berridge, K. C., 1996) injected 6-hydroxydopamine (6-OHDA), a selective neurotoxin for dopamine, bilaterally into the ascending dopaminergic bundle, at a point in the LH where fibers join together from midbrain A9 and A10 sites on their way to the neostriatum and nucleus accumbens. In these rats, dopamine was depleted by 95–99% in both the neostriatum and nucleus accumbens and rats became aphagic. However, positive hedonic reactions to sucrose were not suppressed relative to control levels even in these aphagic rats. Aversive reactions to bitter solutions were also unaltered by these selective dopaminergic lesions.

Electrophysiological experiments also suggest that dopamine neurons in the mesolimbic system are less related to the evaluation of taste palatability. Dopamine neurons in the midbrain including the VTA of the monkey show short, phasic activation in a rather homogenous fashion after the presentation of liquid and food rewards, and visual or auditory stimuli that predict reward, suggesting that these dopamine neurons preferentially report rewarding events (Schultz, W. and Romo, R., 1990). However, these dopamine neurons appear to encode a discrepancy between the prediction of reward (a reward prediction error) rather than reward per se (Ljungberg, T. *et al.*, 1992). Recently, we have found that more than half of the neurons recorded in the

VTA of freely behaving rats change their firing during licking of liquid reward (Shimura, T. *et al.*, 2005). Since there is no difference in the responsiveness to taste solutions and water, these neurons may be involved in fluid reward rather than the hedonic impact of taste.

Shimura T. *et al.* (2002a) showed evidence that the mesolimbic dopaminergic system interacts with the benzodiazepine and/or opioid systems to exhibit the normal intake pattern for palatable fluid. Electrolytic or 6-OHDA lesions of the VTA suppress the consumption of a preferred sucrose or NaCl solution without influencing the intake of other tastes or water. Systemic injections of the benzodiazepine agonist midazolam significantly facilitates the consumption of a preferred sucrose in sham control but not in VTA-lesioned rats. Midazolam does not affect the consumption of an aversive quinine solution in either lesioned or sham animals. Moreover, while systemic administration of morphine, an opioid agonist, selectively increases the consumption of sucrose solution in control rats without affecting the consumption of quinine solution, the intake of both sucrose and quinine solutions remains unchanged by morphine injections in VTA-lesioned rats. These results suggest that the dopaminergic mediation is required for the normal expression of both benzodiazepine- and opioid-induced overconsumption of palatable fluid. According to the current concept that food reward contains distinguishable functional components, liking (palatability) and wanting (incentive motivation) (Berridge, K. C., 1996), the mesolimbic dopamine system seems to mediate wanting rather than liking for food and fluid reward. In fact, hyperdopaminergic dopamine transporter-knockdown mutant mice have higher wanting for a sweet reward in a runway task (Peciña, S. *et al.*, 2003). But sucrose taste fails to elicit higher orofacial liking reactions from mutant mice in an affective taste reactivity test. On the other hand, since sucrose sham feeding increases dopamine levels in the nucleus accumbens in a concentration-dependent manner (Hajnal, A. *et al.*, 2004), the mesolimbic dopamine system seems to be implicated in a reward effect of taste palatability.

4.24.3.3 The Nucleus Accumbens

The nucleus accumbens has long been considered to be an essential interface between motivation and action (Mogenson, G. J. *et al.*, 1980). Neuroanatomical and histochemical studies have revealed that the accumbens is composed of two major subregions, the core, and the shell extending medially, ventrally, and laterally around the core. The functions of core and shell subregions are thought to be different on the basis of distinctive anatomical profiles (Heimer, L. *et al.*, 1991). Considerable evidence has indicated that the nucleus accumbens is critically involved in palatability-induced feeding behavior. The hyperphagic effect of opioids described in the previous section has been shown to be most prominent when opioids are injected into the nucleus accumbens, especially into the shell subdivision. For example, microinjections of DAMGO induce a robust, dose-dependent increase in food intake that is blocked by coadministration of naltrexone (Bakshi, V. P. and Kelley, A. E., 1993). It is noted that the hyperphagic effects of DAMGO are selective to highly palatable taste stimuli such as a high-fat diet (Zhang, M. *et al.*, 1998; Zhang, M. and Kelley, A. E., 2000), sucrose solution (Zhang, M. and Kelley, A. E., 1997), saccharin, NaCl, and ethanol solutions (Zhang, M. and Kelley, A. E., 2002). In addition, morphine microinjections into the nucleus accumbens shell not only facilitates feeding but also selectively increases positive hedonic patterns of behavioral affective reaction elicited by oral sucrose, using the taste reactivity test of hedonic palatability (Peciña, S. and Berridge, K. C., 2000).

The nucleus accumbens receives afferent inputs from corticolimbic and thalamic structures, which are primarily mediated by excitatory amino acids (Robinson, T. G. and Beart, P. M., 1988). Microinjections of 6,7-dinitroquinoxaline-2,3-dione (DNQX), a glutamatergic α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor antagonist, but not the NMDA antagonist 2-amino-5-phosphonopentanoic acid (AP-5), into the medial shell subregion resulted in a pronounced feeding response (Maldonado-Irizarry, C. S. *et al.*, 1995). DNQX significantly facilitates intake of solid and liquid food, but does not significantly affect water intake or gnawing behavior, suggesting that DNQX is acting on a system specifically involved with the regulation of food intake (Stratford, T. R. *et al.*, 1998). Moreover, the feeding response is completely inhibited by concurrent infusion of the $GABA_A$ agonist muscimol into the LH, a major projection area of the accumbens shell (Maldonado-Irizarry, C. S. *et al.*, 1995). These findings demonstrate a selective role for non-NMDA receptors in the nucleus accumbens shell in ingestive behavior and suggest an important functional link between the nucleus accumbens and the LH.

The majority of cells projecting from the accumbens shell are medium spiny neurons that use GABA as a neurotransmitter (Meredith, G. E. *et al.*, 1993). Acute inhibition of cells in the accumbens shell by administration of the $GABA_A$ receptor agonist muscimol or the $GABA_B$ receptor agonist baclofen elicits intense, dose-related feeding without altering water intake (Stratford, T. R. and Kelley, A. E., 1997). Moreover, injections of muscimol into the accumbens shell greatly increase the number of cells exhibiting Fos-like immunoreactivity in the LH (Stratford, T. R. and Kelley, A. E., 1999). Immunohistochemical results show that intra-accumbens shell muscimol treatment increases the percentage of orexin/hypocretin-containing neurons expressing Fos in the lateral hypothalamic area (Baldo, B. A. *et al.*, 2004). The same treatment fails to increase Fos expression in melanin concentrating hormone-containing neurons in the LH. These results suggest that extensive reciprocal interaction between the nucleus accumbens shell and LH regulates feeding behavior.

The VP is a main output target of the GABAergic neuron in the nucleus accumbens. From the VP, GABAergic efferents project to the LH (Groenewegen, H. J. *et al.*, 1993). Thus, the VP is anatomically interposed between neurons in the nucleus accumbens and those in the LH that are known to be intimately related to feeding behavior. Blockade of $GABA_A$ receptors in the VP with bicuculline elicits a strong feeding response in satiated rats without affecting water intake (Stratford, T. R. *et al.*, 1999). Recently, we have found that microinjection of bicuculline into the VP enhances the intake of a preferred saccharin but not quinine solution and water in dehydrated rats, suggesting that the overconsumption produced by GABA blockade in the VP is specific to palatable tastes (Shimura, T. *et al.*, 2006).

Compared to evidence concerning the efferent connections of the nucleus accumbens that may mediate food intake, the role of afferent inputs that convey taste and visceral information to the accumbens are poorly understood. Some anatomical evidence shows that the accumbens receives taste and visceral information through direct input from the NTS in the medulla (Ricardo, J. A. and Koh, E. T., 1978; Saper, C. B., 1982). The accumbens also receives taste information from the insular GC (Brog, J. S. *et al.*, 1993). The amygdala is likely an important source of information about taste and visceral functions to the nucleus accumbens. Taste information received by the central nucleus of the amygdala via the NTS and PBN projects caudally to the VTA, then arrives at the nucleus accumbens. The insular GC – basolateral amygdala – accumbens pathway is also suggested in rats (McDonald, A. J. and Jackson, T. R., 1987; McDonald, A. J. *et al.*, 1999). Because of these afferent as well as efferent connections, the nucleus accumbens appears to be well suited to regulate food intake. Although increasing evidence suggests that the nucleus accumbens shell has a key role for palatability-induced consumption as described above, the precise mechanism for processing of taste palatability in the accumbens is not yet understood.

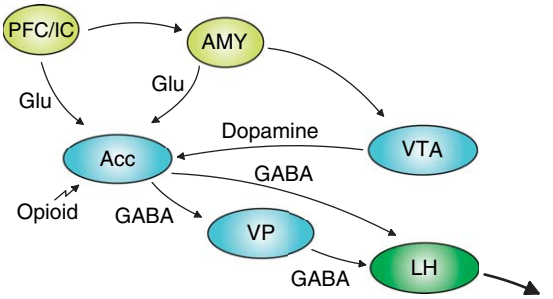

Figure 2 Diagram of reward system responsible for palatability-induced feeding. Glu, glutamate. Other abbreviations are the same as those in Figure 1.

The role of the reward system in palatability-induced feeding is summarized in Figure 2. Taste relays in the lower brainstem are responsible for the palatability shift mediated primarily by benzodiazepines, at least in rodents. Converging corticolimbic input of taste and visceral information to the nucleus accumbens shell is likely involved in mediation of palatability-induced food intake. The GABAergic efferents from the nucleus accumbens shell project to the LH, partly via the VP, so as to regulate the intake of food that is hedonically desirable. Opioid mechanisms in the ventral striatum, especially in the nucleus accumbens, are critically involved in the enhancement of taste palatability. The dopaminergic projection arising from the VTA to the nucleus accumbens is implicated in wanting rather than liking for food and liquid reward.

4.24.4 Role of Taste in Feeding

4.24.4.1 Feeding Behavior to Palatable and Aversive Foods

Substances and liquids with sweet taste, umami taste, and salty taste of hypotonic and isotonic sodium salts are palatable and preferred, while those with sour

taste and bitter taste are aversive and are rejected. Such taste-mediated behaviors have been shown by organisms through the long history of evolution so that sweetness is a signal for energy sources; umami, a signal for protein; saltiness, a signal for minerals; sourness, for rotten food; bitterness, for poisons. These relationships are innately common among different species of animals, that is, human newborn babies show ingestive behavior with mild facial expressions to sweeteners and rejective behavior with aversive expressions to acids and bitter substances, whereas rats show the characteristic oral-lingual movements and body reactions as described in the previous section of this chapter and show a very similar preference–aversion pattern of intake to different sapid solutions as do humans (Figure 3)

The neural substrates for taste-mediated ingestion are basically located in the brainstem without the involvement of higher centers of the gustatory system since similar hedonic reactions to taste stimuli can be seen in anencephalic or hydroanencephalic human infants (Steiner, J. E., 1973) and decerebrate rats (Grill, H. J. and Norgren, R., 1978b). The possible existence of anatomical segregation of taste-responsive neurons in both the qualitative and hedonic aspects of taste at the brainstem level (Yamamoto, T. *et al.*, 1994a) may serve an efficient basis of eliciting quality-specific and hedonic-oriented gustatory reflexes. Other lines of evidence through c-*fos* immunohistological and electrophysiological studies suggest that there are dual separate pathways for sensory and hedonic aspects of taste in each station of the ascending gustatory route including the NTS, PBN, and VPMpc, and in the GC (Sewards, T. V., 2004, for a review).

It is also necessary to add that higher brain centers which may not be directly involved in the processing of gustatory quality discrimination play important roles in evaluation of hedonic values of foods and tastes. As is described in detail in the following sections of this chapter, such regions include the amygdala, orbitofrontal cortex, cingulate cortex, reward system, and hypothalamus.

Besides the innate preference or aversion behaviors, nutrients or minerals that are essential for living organisms will become very palatable, preferred, and craved when those substances are deficient. The well-known and documented instances are salt appetite and amino acid deficiency. When animals are deficient in body sodium, they ingest excessive amounts of salt solutions at high concentrations which are normally avoided. They also increase their intake of lower salt concentrations. The mean response of neurons to NaCl is reduced in the NTS of sodium-deprived rats (Jacobs, K. M. *et al.*, 1988; Nakamura, K. and Norgren, R., 1995). It has further been demonstrated that sodium depletion causes not only lowered responses to NaCl but also an alteration in the neural representation of NaCl (Jacobs, K. M.

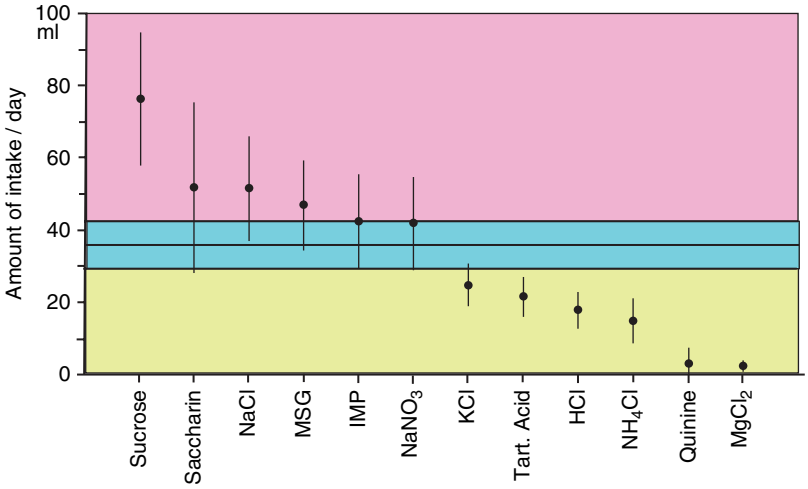

Figure 3 Amount of fluid intake/day for 12 different taste stimuli with the single bottle method in rats. Each value with a vertical line and a horizontal bar with upper and lower horizontal bars (water intake, blue belt) indicates means ± SEs ($n = 15$). The chemicals on the abscissa are arranged from left to right in the order of most to least preferred. If the amount of intake of a stimlus is over the blue belt (within the pink area), the stimulus is preferable, and if within the yellow area, the stimulus is aversive. Adapted from Yamamoto, T., Yuyama, N., Kato, T., and Kawamura, Y. 1985b Gustatory responses of cortical neurons in rats. III. Neural and behavioral measures compared. J. Neurophysiol. 53, 1370–1386.

et al., 1988). As for PBN neurons (Shimura, T. *et al.*, 1997a), taste responses to 0.3 and 0.5 M solutions of NaCl were significantly lower in the sodium-deprived rats than in controls, and correlation coefficients of responses among sodium salts and those between 0.5 M NaCl and sweeteners were larger in the sodium-deprived rats than in controls. These results suggest that PBN neurons in sodium-deprived rats are critically implicated in induction of quantitative and qualitative changes of gustatory sense to sodium salts. Rats display a preference for a particular amino acid when they are deprived of the amino acid. For example, when rats were fed with a lysine-deficient diet, the order of preference was lysine > saline > monosodium glutamate > glycine > threonine > water > arginine > histidine, while in control rats, arginine > saline > monosodium glutamate > glycine > water > threonine > histidine > lysine (Tabuchi, E. *et al.*, 1991). These investigators found that some neurons in the LH responded specifically to lysine when the animals were lysine deficient, suggesting that the LH is involved in mediating the preference for deficient amino acids.

4.24.4.2 Learning and Memory Related to Feeding Behavior

Feeding behavior can be modified by learning through gustatory experience associated with pleasant or unpleasant consequences.

4.24.4.3 Preference Learning

There are two types of learned taste preference: (1) attenuation of neophobia and (2) conditioned taste preference (CTP). When an animal ingests a harmless new substance or liquid, it shows neophobia (see the left in Figure 4) and it increases the consumption at subsequent exposures after learning that the substance is safe to consume (see the upper-right in Figure 4). Through this process of the attenuation of neophobia (or learned safety), foods can be classified as familiar-safe (Nachman, M. and Jones, D. R., 1974; Domjan, M., 1976). Although each part of the gustatory pathway may be concerned with neophobia, since lesions of only one of these parts attenuate neophobia (Yamamoto, T. *et al.*, 1995), a recent study (Bahar, A. *et al.*, 2004) shows that the GC plays an important role in the recognition of whether the taste is familiar or novel. Gutiérrez R. *et al.* (2003) show that cortical muscarinic receptors are important during a 2- to 4-h continuous period in which noxious consequences of food ingestion are absent for the formation and consolidation of learned safety.

When ingestion of a neutral or mildly aversive food is associated with good postingestive visceral sensation, those foods become hedonically positive, or rewarding and preferred. This phenomenon is referred to as CTP (Fanselow, G. and Birk, J., 1982). CTP is attained gradually but more strongly via a flavor conditioning process. Previous studies demonstrated that rats could learn to prefer a taste solution paired with intragastric nutrient infusion (Elizalde, G. and Sclafani, A., 1990), opiate administration (Mucha, R. F. and Herz, A., 1986), and intracranial self-stimulation (Olds, J. and Milner, P. M., 1954). Nutrients can have positive postingestive actions that influence food selection and increase consumption (Sclafani, A., 2004). Giza B. K. *et al.* (1997) showed that the consumption of even an innately aversive $MgCl_2$ solution could be preferred by pairing with a nutrient, polycose, in rats. The rewarding properties of food that promote eating and influence food choice result from the central integration of orosensory and viscerosensory stimuli. The central neural mechanism of association of taste with postingestive food reward is not fully understood. The PBN and LH may play some important roles in flavor preference learning (Sclafani, A. *et al.*, 2001; Touzani, K. and Sclafani, A., 2001). The central dopamine system may also have a critical role in flavor learning (Azzara, A. V. *et al.*, 2001), whereas the involvement of opioid systems is less certain (Azzara, A. V. *et al.*, 2000).

4.24.4.4 Aversion Learning

When ingestion of a substance is followed by malaise such as gastrointestinal discomfort and nausea, associative learning between the ingested substance and internal consequences is quickly established; animals remember the taste for a long time and reject its ingestion on subsequent exposure (see the lower-right in Figure 4). This phenomenon is called a CTA or taste aversion learning.

CTA has the following characteristics, which are distinguished from classical conditioning (Bures, J. *et al.*, 1988): (1) Strong and long-lasting CTAs to novel taste stimuli can be established in a single learning procedure, that is, after one pairing of conditioned stimulus (CS) and unconditioned stimulus (US). (2) Successful CTAs can develop to the CS after delays of as long as 4–12 h between exposure to the CS and delivery of the US. CTA can be considered as a kind of

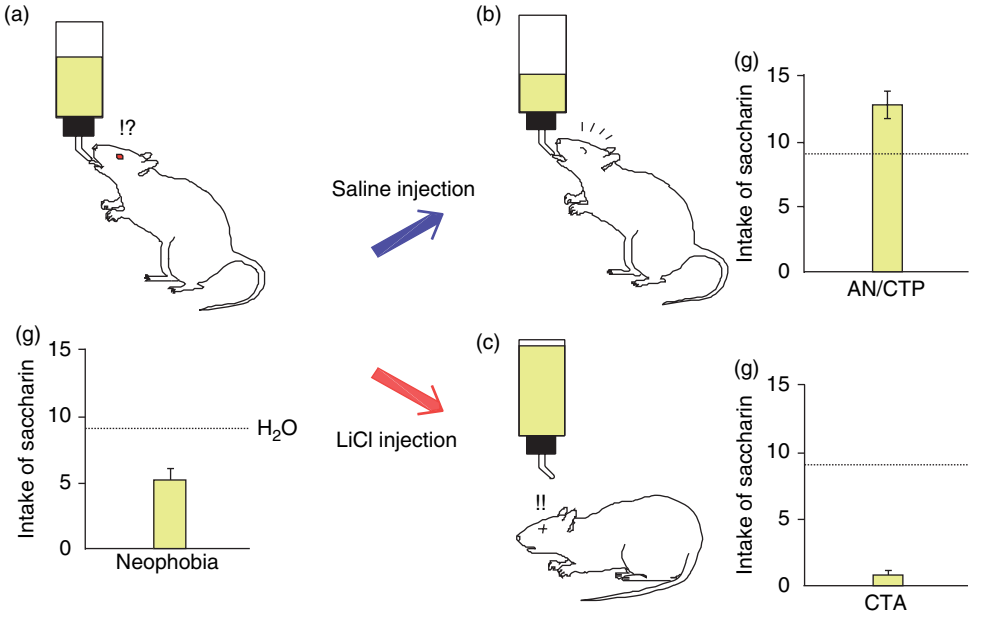

Figure 4 Schematic drawing of neophobia, attenuation of neophobia (AN), conditioned taste preference (CTP), and conditioned taste aversion (CTA). The magnitude of saccharin intake in each graph is taken from Yamamoto, T., Fujimoto, Y., Shimura, T., and Sakai, N. 1995. Conditioned taste aversion in rats with excitotoxic brain lesions. Neurosci. Res. 22, 31–49.

fear learning and serves as a defense mechanism of the organism to avoid ingestion of harmful substances. CTA is easily acquired in humans as well, for example, our survey (unpublished) for Osaka University students shows that a significant proportion of their food dislikes is based on CTA acquired before the middle grade of the elementary school (or below 10 years old). After the acquisition of CTA to an artificial sweetener, saccharin, this sweet and palatable substance still tastes sweet but changes to an aversive stimulus. Taste quality may not change, but the hedonic aspect changes drastically. This fact may indicate the existence of separate neural representations of the sensory aspects and the hedonic aspects of taste in the gustatory pathway (Sewards, T. V., 2004 for a review). Although the neural substrate and the molecular mechanisms of CTA have recently been well studied (Yamamoto, T. *et al.*, 1994b; Bures, J. *et al.*, 1998; Yamamoto, T. *et al.*, 1998; Bermúdez-Rattoni, F., 2004; Yamamoto, T., 2007 for reviews), a detailed discussion of the contribution of the different brain regions to formation of the CTA is outside the scope of this review except for the following few topics.

Electrophysiological studies of unit activity in GC neurons in freely ingesting and anesthetized rats have revealed that the GC processes multiple aspects of taste-related responses including sensory and hedonic responses (Yamamoto, T. *et al.*, 1989a), convergent responses (Yamamoto, T. *et al.*, 1988; 1989a; Hanamori, T. *et al.*, 1998), temporal responses (Katz, D. B. *et al.*, 2001), anticipation (Yamamoto, T. *et al.*, 1988), and familiarity (Bahar, A. *et al.*, 2004). These response characteristics of GC neurons may not only contribute to the acquisition and retention of CTA but may be actively involved in the formation of CTA as revealed by occurrence of short-term and long-term potentiated responses to the CS after pairing its ingestion with the US (LiCl) (Yamamoto, T. *et al.*, 1989a; Yasoshima, Y. and Yamamoto, T. 1998). The amygdala is one of the most important areas in the integration of the CS and US. Yamamoto T. *et al.* (1994b), Yamamoto T. *et al.* (1995), and Yasoshima Y. *et al.* (2006) found that the basolateral nucleus was more important in the acquisition and retention of CTA in comparison with the central nucleus of the amygdala. Electrical stimulation of the central nucleus enhanced the responsiveness of the PBN neurons that responded best to the CS (Tokita, K. *et al.*, 2004). Taking these results together with those from other literature, it is plausible that the basolateral amygdala, which is involved in the formation of fear learning (Maren, S. and Fanselow, M. S., 1996 for a review), is important in the hedonic shift from palatable to aversive, and that the central nucleus,

which is known to receive taste inputs together with other sensory inputs, contributes to the enhancement of gustatory responses to the CS (Shimura, T. *et al.*, 1997b; 2002b; Tokita, K. *et al.*, 2004), which facilitates detecting and avoiding the harmful substance.

4.24.4.5 Orexigenic Substances

Palatability is one of the most important factors that regulates food and fluid intake. Animals usually prefer innately palatable sweet-tasting substances, and their consumption often exceeds the need for homeostatic repletion. The effects of palatable food on feeding behavior may be related to functions of the newly identified chemical mediators that regulate appetite, for example, orexins (orexin-A and -B), melanin-concentrating hormone (MCH), agouti-related protein (AgRP), ghrelin, and neuropeptideY (NPY), all of which are known to stimulate feeding and thus, to function as orexigenic peptides (Inui, A., 2000; Schwartz, M. W. *et al.*, 2000). These peptides are produced in the hypothalamus and are well studied in terms of feeding, energy homeostasis, and obesity. Among these peptides, Furudono Y. *et al.* (2006) have suggested that orexin-A, NPY, and MCH are involved, in this order of effectiveness, in palatability-induced ingestion on the bases of the following. Administration of orexin-A into the lateral ventricle in rats increased both water and saccharin intake compared to vehicle administration. Similarly, administration of MCH increased the intake of both fluids. However, NPY injections enhanced only the intake of saccharin. These results suggest that orexin-A, MCH, and NPY are related to the facilitation of drinking. On the other hand, ghrelin and AgRP had no effects on fluid intake. When the changes in mRNA levels for orexin, NPY, and MCH in the hypothalamus were examined after drinking saccharin or water, saccharin, but not water, facilitated an increase in the orexin and NPY mRNA levels. MCH mRNA levels did not differ between saccharin and water intake and remained stable. Increased ingestion may be closely related to enhanced digestive functions. To address this issue, Kobashi M. *et al.* (2003) examined the effects of intraventricular injections of orexin-A on gastric motility. They measured the motility changes as alterations in intragastric pressure, by means of two balloons in the proximal and distal parts of the stomach (Kobashi, M. *et al.*, 2000). The proximal stomach is known to function as a reservoir, whereas the distal stomach's main function is to stir and drain gastric contents. Orexin-A induced strong rhythmical gastric motility in the distal stomach, while the vehicle had no effect. Since the function of the distal stomach is to stir and discharge gastric contents, gastric motility induced by orexin-A may facilitate digestive function. In the proximal stomach, orexin-A induced relaxation, while the vehicle had no effect. It is suggested that the relaxation of the proximal stomach enables it to accept more food, and the facilitation of phasic contractions of the distal stomach accelerates draining of the increased gastric contents. Thus, it is plausible that the orexigenic action of orexin-A accompanies the activation of digestive function. These results may answer a common question about why you can eat palatable sweet-tasting foods faster and in larger amount than neutral or unpalatable foods.

4.24.5 Brain Imaging Study on Hedonic Evaluation in Humans

When we wish to analyze the role of taste in feeding and reward in humans, the most suitable method now available is the noninvasive brain imaging techniques such as functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and magnetoencephalography (MEG).

A single chemical solution placed into the mouth can elicit both sensory (or qualitative) perception and hedonic (preferred or aversive) feeling, for example, sucrose is sweet and palatable, while 1 M NaCl is salty and aversive and quinine hydrochloride is bitter and aversive. Therefore, we can analyze sensory and/or hedonic aspects when these taste stimuli are used.

A number of researchers have identified the primary taste area (PTA) in the opercular-insular cortex by using fMRI (Faurion, A. *et al.*, 1999; O'Doherty, J. *et al.*, 2001; Schoenfeld, M. A. *et al.*, 2004), PET (Kinomura, S. *et al.*, 1994; Small, D. M. *et al.*, 1999 for a review), and MEG (Kobayakawa, T. *et al.*, 1996; Yamamoto, C. *et al.*, 2003; 2006). One of the issues in the PTA concerning taste quality representation is the existence of chemotopy, that is, topographic arrangement of taste responsiveness to each of the five basic tastes: sweet, umami, salty, sour, and bitter. In spite of the limitations of analysis due to the anatomical position and small size of the PTA, Schoenfeld M. A. *et al.* (2004) used the fMRI method and showed the possible existence of chemotopy with a high interindividual variability, although with some considerable overlap. They reported that

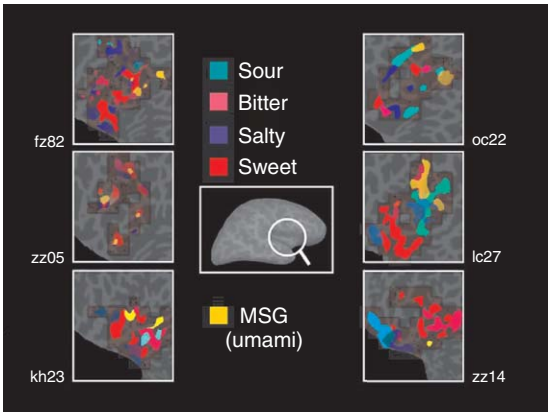

Figure 5 The functional magnetic resonance imaging (fMRI) analysis of the topography of hemodynamic activity elicited by citric acid (sour), caffeine (bitter), NaCl (salty), sucrose (sweet), and monosodium glutamate (umami) on the flattened cortical surfaces of the insular/opercular cortex (encircled area in the center of the figure) of the right hemisphere of six human subjects. Each panel corresponding to each subject shows a composite pattern of responses to multiple stimulations with each of the five taste stimuli denoted by the different colors. Note the different patterns of hemodynamic activity for the five tastes with considerable overlap and a high interindividual topographical variability. Taste-specific patterns, however, were stable over time in each subject. From Schoenfeld, M. A., Neuer, G., Tempelmann, C., Schüßler, K., Noesselt, T., Hopf, J. M., and Heinze, H. J. 2004. Functional magnetic resonance tomography correlates of taste perception in the human primary taste cortex. Neuroscience 127, 347–353.

the taste-specific patterns as shown in Figure 5 were stable over time in each subject. The existence of chemotopy and implication of its importance in taste quality discrimination have been implicated in the rat GC (Yamamoto, T. *et al.*, 1985a; 1985b; 1989a; Yoshimura, H. *et al.*, 2005; Accolla, R. *et al.*, 2007) and suggested in the monkey PTA (Scott, T. R. *et al.*, 1986).

The PTA is involved not only in receiving and processing of taste inputs for qualitative and quantitative discrimination of taste stimuli but also in gustatory imagery by recalling gustatory memories. According to Kobayashi M. *et al.* (2004) in fMRI study, there is an asymmetrical topography of activation in the insula: the left insula is predominantly activated by gustatory imagery tasks, while the right insula, by actual gustatory stimulation in the mouth.

Recent fMRI and PET studies have shown that human amygdala responds specifically to negative emotion, especially to facial expressions of anger, fear, or sorrow (Hyman, S. E., 1988). There is a report, however, that the left amygdala is activated by a facial expression of fear and right amygdala is activated by an expression of happiness (Morris, J. S. *et al.*, 1996). Unpleasant odor stimulation also activates the amygdala. Zald D. H. and Pardo J. V. (1997) showed that strong unpleasant odor of sulfate compounds activated the bilateral amygdala and left orbitofrontal cortex. There are high correlations among the left amygdala, left orbitofrontal cortex, and perceived aversive feeding, indicating strong functional interactions between the amygdala and orbitofrontal cortex and important roles in emotional evaluation of odor.

Concerning the activation of the amygdala by taste stimulation in humans, Zald D. H. *et al.* (1998) reported in a PET study that 1 M NaCl, a strong and aversive taste stimulus, activated the right amygdala and neutral water and palatable chocolate induced no response in the amygdala, suggesting that the amygdala is responsive to aversive stimuli. Further, Zald D. H. *et al.* (2002) showed in a PET study that bitter and aversive quinine (0.02 M), but not sweet and palatable sucrose (30%), induced big responses in the left amygdala. Both quinine and sucrose excited the right posterior part of the orbitofrontal cortex, but the left inferior frontal pole and the anterior part of the orbitofrontal cortex were activated only by quinine stimulation. On the other hand, O'Doherty J. *et al.* (2001) found in fMRI study that both pleasant (1 M glucose) and unpleasant (0.1 M NaCl) taste stimuli evoked responses in the amygdala and orbitofrontal cortex, but the areas activated were different between the two stimuli. Thus, the activated areas are not consistent among researchers.

As already described, a flavor, taste-odor integration is very important in the sensory evaluation of foods. Small D. M. *et al.* (1997) in a PET study found that mismatched combinations such as salty and strawberry, sour and coffee, sweet and soy sauce, bitter and grapefruit, in contrast to the matched combinations such as salty and soy sauce, bitter and coffee, sour and grapefruit, sweet and strawberry, induced stronger activation in the left amygdala and the bilateral forebrain basal area. From these results, they suggest that these areas are important in processing of neophobic or unpleasant taste stimuli. In a further study using fMRI technique, Small D. M. *et al.* (2004) observed superadditive responses during the perception of the congruent flavor (vanilla/sweet) compared with the sum of its constituents in the anterior cingulate cortex, dorsal insular, anterior ventral insular extending into the caudal orbitofrontal cortex, frontal operculum, ventral lateral PFC, and posterior parietal cortex. Taken together with

previous findings in the literature (O'Doherty, J. *et al*., 2001; Small, D. M. *et al*., 2001; Zald, D. H. *et al*., 2002), their results suggest that the insular, orbitofrontal, and anterior cingulate cortices are key components of the network underlying flavor perception.

4.25.1 Ingestive Behavior and Reward

Sucrose is a prototypical reward in animal behavior studies. It is a simple compound, can be delivered easily in water, and sustains reliable performance without food or water restriction. Under ordinary circumstances, humans report sucrose as sweet and pleasurable. The generality of this experience allows scientists to infer that similar subjective events occur in other animals. In behavioral terms, reward is defined operationally as an event – a stimulus – that increases the probability of a contiguous response being emitted again (Thorndike, E., 1911). When studying the neural bases for reward, however, operational definitions are less satisfactory because the goal is to understand the so-called intervening variable, that is, what humans term pleasure.

The normal behavioral response to sucrose is ingestion. It is organized in the caudal brainstem because the entire sequence appears in anencephalic infants and chronically decerebrate rats neither of which have functional forebrains (Steiner, J. E., 1973; Grill, H. J. and Norgren, R., 1978a). In decerebrate rats, ingestion and rejection are near normal but largely stimulus bound (Grill, H. J. and Norgren, R., 1978b). Although short-term plasticity can occur, behavior in decerebrates cannot be altered permanently by experience (Grigson, P. S. *et al.*, 1997). The forebrain is necessary for learning and memory to influence consummatory behavior. This influence can be manifested in the consummatory behavior itself, such as with a learned preference or aversion (Sclafani, A., 1997). More frequently, the influence of learning appears in the appetitive phase, as when a deprived animal returns to a place where it had previously encountered food (Craig, W., 1918). Thus, the forebrain is necessary for the full expression of the motivation and reward systems that activate and direct the appetitive behavior needed to bring the animal into contact with the consummatory stimuli (Norgren, R. *et al.*, 2003).

In short, the neural circuits needed for discriminative ingestion and rejection behavior are complete in the brainstem. The systems that animate adaptive behavior in the real world – learning, memory, motivation, and reward – require the forebrain. Therefore, in order to investigate the neural basis for sucrose reward, we must identify an index for this function that depends on the forebrain and is not directly related to behavior. Although far from perfect, the best candidate available is dopamine release, specifically in the nucleus accumbens (NAcc; Ikemoto, S. and Panksepp, J., 1999; Wise, R. A., 2005).

4.25.2 Dopamine and Reward

The neural substrate for reward remains a challenge because the concept itself is illusive. Despite this limitation, extensive research has been devoted to the neural bases of reward. As a result, a network of nuclei and neurotransmitters has been identified that influence reward functions, even if the nature of that influence is far from settled. Among the most studied of these putative reward substrates is the mesolimbic or mesoaccumbens dopamine system. Experimental manipulations of this system disrupt behavior guided by both natural and non-natural rewards (Smith, G. P., 1995; Wise, R. A., 2002). Conversely, both natural and drug rewards activate this pathway (Smith, G. P., 1995; Wise, R. A., 2002; 2005) which originates from the

ventral tegmental area (VTA) of the brainstem (Oades, R. D. and Halliday, G. M., 1987). Although its role in reward is debated (Berridge, K. C. and Robinson, T. E., 1998; Cannon, C. M. and Palmiter, R. D., 2003), no one denies that dopamine release occurs in the mesoaccumbens dopamine system when normally preferred stimuli are presented to an animal. The contention arises over interpreting the significance of the release. Does it signify a broader phenomenon, such as arousal, attention, learning, or reward, or a more restricted category, such as uncertainty, novelty, expected value, or incentive (Di Chiara, G., 1998; Ikemoto, S. and Panksepp, J., 1999; Salamone, J. D. *et al.*, 2003; Schultz, W., 2005; Wise, R. A., 2005)? In what follows, and particularly in our own work, we assume only that dopamine release tracks the incentive valence of reward, that it provides a forebrain index of sensory events that the animal will work to obtain.

The presentation or even the anticipation of food stimulates dopamine neurons in the VTA and dopamine release preferentially in the shell of the NAcc (Church, W. H. *et al.*, 1987; Hernandez, L. and Hoebel, B. G., 1988a; 1988b; Radhakishun, F. S. *et al.*, 1988; Yoshida, M. *et al.*, 1992; Inoue, K. *et al.*, 1993; Westerink, B. H. *et al.*, 1994; Wilson, C. *et al.*, 1995). In addition to the NAcc, food intake results in dopamine release in other terminal regions of the VTA projections such in the prefrontal cortex (Hernandez, L. and Hoebel, B. G., 1990; Feenstra, M. G. and Botterblom, M. H., 1996) and the central nucleus of the amygdala (Hajnal, A. and Lenard, L., 1997). Although imaging methods have been useful, primarily in human studies (Wang, G. J. *et al.*, 2002; McClure, S. M. *et al.*, 2004; Rolls, E. T., 2005), the majority of available data derive from *in vivo* microdialysis studies, a method that permits direct measurement of central dopamine release and metabolism during behavior (Hoebel, B. G. *et al.*, 1989; Westerink, B. H., 1995). Dialysis typically requires 5–20 min samples to detect significant changes in dopamine flux. Advances in voltammetry have decreased the detection threshold during ingestive behavior into the millisecond range (Kiyatkin, E. A. and Gratton, A., 1994; Roitman, M. F. *et al.*, 2004).

4.25.3 Dopamine and Sucrose Preference

During ingestion dopamine release in the NAcc is a function of the oral stimulus, previous experience, and motivational state (Bassareo, V. and Di Chiara, G., 1997; 1999; Norgren, R. *et al.*, 2003; Smith, G. P., 2004). Most relevant feeding experiments were performed under deprivation condition that by itself augments the incentive value of external stimuli (Carr, K. D., 1996; Pothos, E. N., 2001). Deprivation also prevents habituation of accumbens dopamine release (i.e., latent inhibition) after repeated exposure to ingestive stimuli (Bassareo, V. and Di Chiara, G., 1999). Nevertheless, rats fed *ad libitum* on standard food still exhibit an increase of NAcc dopamine when given a more preferred diet (Ahn, S. and Phillips, A. G., 1999; Cenci, M. A. *et al.*, 1992; Mitchell, J. B. and Gratton, A., 1992; Wilson, C. *et al.*, 1995). In fact, highly preferred food itself reliably elicits an increase in the extracellular dopamine in the NAcc (Mark, G. P. *et al.*, 1991; Mitchell, J. B. and Gratton, A., 1992; Hajnal, A. and Norgren, R., 2001) and also increases somatodendritic dopamine release in the VTA, where the mesoaccumbens pathway originates (Zhang, H. *et al.*, 1994). Moreover, repeated access to palatable sucrose solution consistently results in dopamine release in the NAcc over several days (Hajnal, A. and Norgren, R., 2001; 2002; Rada, P. *et al.*, 2005), an effect that can be reproduced even when the postabsorptive effects are eliminated using sham feeding preparation (Hajnal, A. *et al.*, 2004a). This observation supports the notion that dopamine tracks the hedonic value of an (oro)sensory stimulus.

Another indication that dopamine influences feeding behavior in general and sucrose preference in particular comes from studies that interfere with the postsynaptic receptors for this neurotransmitter. Systemic injection of D1 and D2 dopamine receptor antagonists reduced both real and sham feeding of sucrose (Geary, N. and Smith, G. P., 1985; Smith, G. P. and Schneider, L. H., 1988; Schneider, L. H., 1989; Cooper, S. J. *et al.*, 1993; Duong, A. and Weingarten, H. P., 1993; Hsiao, S. and Smith, G. P., 1995). Learned preference for sucrose also is decreased with administration of dopamine receptor antagonists (Yu, W. Z. *et al.*, 2000a; 2000b). Furthermore, dopamine-deficient (DD) mice can eat but are not motivated to do so (Szczypka, M. S. *et al.*, 1999b), suggesting that DD mice are unable to integrate and process the neuronal signals necessary to stimulate and maintain feeding. In fact, dopamine replacement re-establishes preference for sucrose in DD mice (Szczypka, M. S. *et al.*, 1999a). Lesions to the VTA also have been shown to reduce sucrose preference (Shimura, T. *et al.*, 2002). These studies demonstrate that dopamine and its receptors are important for initiating and maintaining sucrose

ingestion, but they do not reveal where in the brain (or the body) these actions take place.

The opposite relationship, that is, that sucrose intake can be increased by pharmacological manipulation, provides more specific information. In this case, nomifensine, a blocker of dopamine uptake, infused into the accumbens by reverse microdialysis increased dopamine in the accumbens and increased sucrose intake (Hajnal, A. and Norgren, R., 2001). Although nomifensine also affects other monoamine transporters, low doses of the dopamine receptor antagonists SCH 23390 and sulpiride dialyzed together with the reuptake blocker into the accumbens abolished both the increased dopamine and the increased sucrose licking (Hajnal, A. and Norgren, R., 2001).

Less specific evidence for accumbens dopamine modulating reward arises from the cross-sensitization effects of sucrose and the indirect dopamine agonist amphetamine. Compared with NaCl-treated controls, rats previously sensitized to amphetamine increased their locomotor activity after brief access to sucrose (Avena, N. M. and Hoebel, B. G., 2003a). Similarly, rats receiving restricted sucrose access exhibited higher locomotor activity when subsequently injected with amphetamine (Avena, N. M. and Hoebel, B. G., 2003b; Hajnal, A. *et al.*, 2004b). In addition, rats that spontaneously ingested more sucrose showed increased amphetamine-induced dopamine overflow in the caudal NAcc relative to those that licked less sucrose (Sills, T. L. and Vaccarino, F. J., 1996). These studies imply a reciprocal relationship between dopamine flux and ingestion of sucrose. Dopamine tracks sucrose intake even if the causal direction is less obvious.

Direct measures of accumbens dopamine during sucrose ingestion are surprisingly scarce. Oddly, indirect measures are the norm. In these experiments, accumbens dopamine is more often measured using a conditioned stimulus that was paired with sucrose or some other normally preferred chemical such as saccharin. In naive rats licking a saccharin solution causes an increase in accumbens dopamine, measured with microdialysis (Mark, G. P. *et al.*, 1991; Grigson, P. S. *et al.*, 2004). Fructose has similar effects in rats (Hajnal, A., personal communication). Both saccharin and fructose taste sweet to humans, are preferred by rats (Sclafani, A. and Nissenbaum, J. W., 1985; Sclafani, A. and Mann, S., 1987; Sclafani, A. *et al.*, 1998), and exert reinforcing effects when used as conditioned stimuli (Sclafani, A. and Ackroff, K., 1994). Microdialysis experiments with unconditioned sucrose, however, have been done only recently in our laboratory.

In the first experiment, we established the effect of sucrose ingestion on dopamine in the NAcc. Rats were placed on a 16 h water deprivation schedule and trained to lick either water or 0.3 M sucrose for 20 min each morning for about 1 week. Then the microdialysis probes were inserted into the caudomedial NAcc and left in place for 3 days. The fluid access schedule was continued as before, that is, each rat had access to water and sucrose at least once. Although deprived overnight (~18 h), ingesting water failed to alter dopamine levels. Licking 0.3 M sucrose for 20 min, however, produced a 300% increase in dopamine overflow in the NAcc (Hajnal, A. and Norgren, R., 2001). The effect was impressive, but linking it directly to the reward value of sucrose was not that straightforward. The rats ingested considerably more sucrose solution than water and, even in 20 min, the sucrose would have produced metabolic feedback to which the brain was sensible. To control for these possibly confounding effects, we did two further experiments using essentially the same paradigm.

First, we trained rats to sham feed sucrose – the rats lick normally from a spout, but the fluid drains from a chronic gastric fistula. Then they were allowed to sham lick three different concentrations of sucrose, while accumbens dopamine release was assessed by microdialysis. Even without significant metabolic consequences, accumbens dopamine increased as a function of sucrose concentration. In a third set of rats, we again varied concentration, but clamped total intake during the 20 min sampling period to 75% of what each rat normally ingested of the weakest solution. Even with ingested volume controlled, accumbens dopamine release rose as a function of increasing sucrose concentration (Hajnal, A. *et al.*, 2004a). If we operationally define hedonic value by relative preference, then sucrose reward varies directly with its concentration because, in brief access tests, rats prefer stronger solutions to weaker ones (Davis, J. D., 1973; Spector, A. C. *et al.*, 1993; Contreras, R. J. *et al.*, 1995). Because accumbens dopamine release also varies directly with sucrose concentration, we can take these values as a forebrain index of gustatory reward. Although the exact relationship between dopamine and reward remains undetermined, this effect is sufficient to propose NAcc dopamine as a tool to track capacity of taste stimuli to engage motivational systems.

4.25.4 Central Pathways of Sucrose Reward

Intraoral intake of sucrose increases dopamine in the nucleus of the solitary tract (Bednar, I. *et al.*, 1994), the first central relay of the gustatory system (Lundy, R. F., Jr. and Norgren, R., 2004b). The NAcc receives axonal projections from the caudal part of the nucleus of the solitary tract, but the taste neurons are in the rostral half of the nucleus (Zagon, A. *et al.*, 1994). The accumbens also sends reciprocal projections to the nucleus of the solitary tract (Brog, J. S. *et al.*, 1993; Stratford, T. R. and Kelley, A. E., 1999) via a circuit that includes the parabrachial nucleus (PBN; Usuda, I. *et al.*, 1998). Given its distribution, the involvement of this direct loop in gustatory functions is conceivable, but unlikely. In rodents, the major rostral projection of gustatory neurons is from the anterior aspect of the nucleus of the solitary tract to the caudomedial PBN. From the PBN, the central gustatory system bifurcates, one arm forming a standard thalamocortical axis, the other distributing widely in the limbic forebrain (Lundy, R. F., Jr. and Norgren, R., 2004a). The PBN, which includes the second central gustatory relay, projects densely to the central nucleus of the amygdala, the lateral hypothalamus, and the bed nucleus of the stria terminalis (Norgren, R., 1976; 1978), all of which send axons to the NAcc shell (Kirouac, G. J. and Ganguly, P. K., 1995). The thalamocortical gustatory system can also reach NAcc via substantial connections to the central nucleus of the amygdala, lateral hypothalamus, and the prefrontal cortex (Kosar, E. *et al.*, 1986; Shi, C. J. and Cassell, M. D., 1998; Lundy, R. F., Jr. and Norgren, R., 2004b).

Because all these areas figure prominently in theories of motivation and reward, we decided to determine which forebrain taste pathway supported the release of dopamine in the NAcc during sucrose licking (Pfaffmann, C. *et al.*, 1977). After bilateral lesions of the thalamic taste relay, the accumbens dopamine response during sucrose ingestion was identical to that of sham-operated controls. After similar damage in the PBN, sucrose licking elicited less than one-third of the NAcc dopamine as the controls (Figure 1; Hajnal, A. and Norgren, R., 2005).

We performed another, similar experiment using immunohistochemical staining of Fos, the nuclear phosphoprotein product of the early-immediate gene c-Fos (Mungardee, S. S. *et al.*, 2004). After having similar, bilateral lesions the PBN or the thalamic

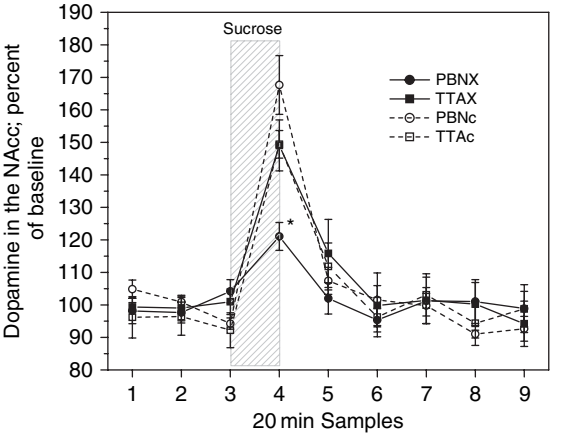

Figure 1 Extracellular levels of dopamine in the nucleus accumbens (NAcc), expressed as a percentage of mean baseline (± standard error of the mean) before, during, and after a 20 min presentation of 0.3 M sucrose (bracket). The rats received ibotenic-acid microlesions in the parabrachial nucleus PBN (PBNX), the thalamic taste area (TTAX), or control surgeries using physiological NaCl injections to the same areas (PBNc, TTAc). Asterisk denotes statistically significant difference based on *post hoc* comparisons between groups ($^{*}P < 0.01$). Adapted from Hajnal, A. and Norgren, R. (2005) Taste pathways that mediate accumbens dopamine release by sapid sucrose. Physiol. Behav. 84, 363–369, with permission from Elsevier.

taste relay, rats were allowed to sham-feed sucrose or water for 1 h. Their brains were then cut and stained for the Fos protein. In the controls and the rats that received thalamic lesions (Figure 2), sham-licking sucrose produced more Fos in the shell of the NAcc than did ingestion of water. In contrast, lesions of the gustatory PBN reduced the overall level of Fos staining and eliminated the differential effect of licking sucrose (Figure 2). These complimentary data represent the first demonstration that the affective character of a sensory stimulus might separate from the thalamocortical stream as early as the second central synapse.

Knowing the pathways through which a normally preferred taste influences a forebrain index of reward says little about the sensory signal that elicits the effect. Sucrose appears to be inherently rewarding. Nevertheless, a full gastrointestinal tract can reduce sugar intake to near zero, implying that the sensory signal no longer is preferred. Conversely, during a negative sodium balance, a normally rejected 0.5 M NaCl solution is avidly consumed. In fact, for most stimuli, reward value is imposed either through learning or through the physiological state of the animal. This could be accomplished by altering the

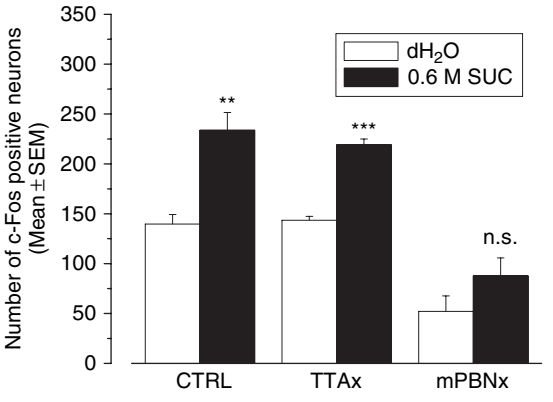

Figure 2 Number of c-Fos positive neurons in the shell of the nucleus accumbens after ibotenic acid microlesions to the thalamic taste area (TTAx) or the medial PBN (mPBNx) in rats exposed to sham drinking of 0.6 M sucrose (SUC) or water (dH_2O). Asterisks denote results from *post hoc* analysis (**, $P < 0.01$; ***, $P < 0.001$; n.s., not significant; SEM, standard error of the mean).

sensory message itself, before it engages the motivation and reward systems, by gating the message within those systems, or both.

We have examined the former proposition because the convergence of visceral afferent, gustatory, and forebrain centrifugal systems in the brainstem relays provides the anatomical framework for such an interaction. Alterations in the response properties of taste neurons in the nucleus of the solitary tract and in the PBN are coincident with behavioral changes in hedonic value (Norgren, R. *et al.*, 2003). For instance, intraduodenal lipid infusions, which reduces intake of sucrose (Foster, L. A. *et al.*, 1996), also decreased the response of PBN sucrose-best cells to sucrose by 55%, but was without effect on sucrose-evoked responses in other cell types (Hajnal, A. *et al.*, 1999). Similar if less specific modulation of taste processing also can be produced by inducing a negative sodium balance or by activating descending projections from reciprocally connected forebrain regions such as the lateral hypothalamus, central amygdala, and the gustatory cortex (Contreras, R. J., 1977; Nakamura, K. and Norgren, R., 1995; Lundy, R. F., Jr. and Norgren, R., 2001; Cho, Y. K. *et al.*, 2002; 2003; Tamura, R. and Norgren, R., 2003; Lundy, R. F., Jr. and Norgren, R., 2004a; Li, C. S. *et al.*, 2005). These observations demonstrate that both physiological and forebrain modulation occur before gustatory neural gustatory activity reaches the mesoaccumbens dopamine system. Whether or not this modulation influences the capacity of tastes to release dopamine, much less their hedonic tone, remains to be determined.

4.25.5 Chronic Effects of Sucrose Ingestion

So far we have discussed only the acute effects of oral sucrose stimulation. In addition to short-term dopamine activation, ingestion of preferred foods, such as glucose or sucrose may result in a lasting neuroadaptation within the mesoaccumbens dopamine system (Colantuoni, C. *et al.*, 2001; Avena, N. M. and Hoebel, B. G., 2003b). We observed that, after as few as 6 days, scheduled, daily, 20 min access to 0.3 M sucrose results in upregulation of the dopamine membrane transporter and downregulation of the D2 dopamine receptors (Bello, N. T. *et al.*, 2002; 2003). Although the function of this neuroadaptation is not clear, accumulating evidence supports the hypothesis that dopamine plays an important role metabolic regulation and energy balance, including in human obesity (Figlewicz, D. P. *et al.*, 1994; 1996; 1998; Patterson, T. A. *et al.*, 1998; Wang, J. *et al.*, 2001; Wang, G. J. *et al.*, 2002; Wang, J. *et al.*, 2002). Chronic food restriction reduces basal dopamine levels in rats and increases consummatory responses to both food and drug rewards (Pothos, E. N. *et al.*, 1995). Similar manipulations also increase bingeing on palatable meals (Hagan, M. M. and Moss, D. E., 1997). Finally, we demonstrated that blocking dopamine reuptake in NAcc of deprived rats accentuates sucrose intake (Hajnal, A. and Norgren, R., 2001). Taken together, these data indicate that dopamine and the NAcc contribute to the control of feeding behavior in part through influencing preference.

4.25.6 Sucrose Reward without Dopamine

It is important to remember that we use accumbens dopamine flux as an index of reward, not as its equivalent. The most dramatic proof of this distinction comes from genetically engineered mice that never produce dopamine, but exhibit near normal sucrose preferences (Cannon, C. M. and Palmiter, R. D., 2003). Opioids are clearly involved with affective responses and, within the NAcc, they may be responsible for the hedonic modulation of taste information (Kelley, A. E. *et al.*, 2002). Opioid antagonists reduce intake of palatable foods in real (Cooper, S. J.,

1982; 1983; Cooper, S. J. *et al.*, 1985; Lynch, W. C., 1986) and sham feeding (Kirkham, T. C. and Cooper, S. J., 1988; Kirkham, T. C., 1990). They also decrease oral motor responses to sucrose in the taste reactivity test (Parker, L. A. *et al.*, 1992). Conversely, when given intermittent access to sugar solutions, rats exhibit increased binding of μ-1 opioid receptors in the NAcc (Colantuoni, C. *et al.*, 2001). Similar evidence exists for serotonin, neuropeptide Y, cholecystokinin, leptin, and acetylcholine, among others (Waldbillig, R. J. and Bartness, T. J., 1982; Gosnell, B. A. and Hsiao, S., 1984; Montgomery, A. M. and Burton, M. J., 1986; Leibowitz, S. F. *et al.*, 1992; Eckel, L. A. and Ossenkopp, K. P., 1994; De Jonghe, B. C. *et al.*, 2005; Hajnal, A. *et al.*, 2005; Kelley, A. E. *et al.*, 2005). All of these factors ultimately may affect the activation of the mesoaccumbens dopamine system, but the relationships are not simple.

Even if the final common path for all these other neurotransmitters does include dopamine, many of them also influence the code for gustatory afferent activity more directly, even at the level of the taste buds. Specifically, neuropeptide Y, cholecystokinin, acetylcholine, and serotonin receptors all have been identified on taste receptor cells (Herness, S. and Chen, Y., 1997; Herness, S. *et al.*, 2002; Huang, Y. J. *et al.*, 2005; Ogura, T. and Lin, W., 2005; Zhao, F. L. *et al.*, 2005). Insulin and leptin receptors also occur on taste receptor cells (Shigemura, N. *et al.*, 2003; Suzuki, Y. *et al.*, 2005). In fact, leptin receptors occur exclusively on sweet taste receptor cells. The exaggerated sweet preference seen in some obese animal models might be related to a malfunction in these leptin receptors (Kawai, K. *et al.*, 2000; Ninomiya, Y. *et al.*, 2002; Shigemura, N. *et al.*, 2004). In normal mice, administration of leptin suppresses single fiber responses in the chorda tympani and glossopharyngeal nerves to sucrose and saccharin but not to other stimuli (Kawai, K. *et al.*, 2000). These direct peripheral effects on the taste system illustrate the multiple systems that can influence gustatory coding. All of these neurotransmitters and peptides play important parts in the control of ingestive behavior and energy balance. Thus, they are obvious candidates for mediating the hedonic tone of taste whose biologic role is to arbitrate ingestion and rejection behavior.

4.25.7 Summary

Sucrose ingestion releases dopamine within the NAcc. This response is concentration dependent, but does not require gastrointestinal or metabolic feedback. This central response arises from the oral gustatory properties of sucrose. Specifically, the accumbens response appears to reflect the hedonic character of sweet stimuli in general. When saccharin is made aversive by association with visceral malaise, this stimulus switches from increasing extracellular dopamine to inhibiting its release (Mark, G. P. *et al.*, 1991). While sucrose licking does increase dopamine release, the obverse also is true. Increasing dopamine availability in the NAcc increases intake of sucrose solutions and blocking D1 dopamine receptors inhibits it (Hajnal, A. and Norgren, R., 2001).

Despite these close relationships, a direct causal link between taste and reward in the accumbens is unlikely. Sucrose intake is not compromised by dopaminergic lesions and is near normal in dopamine knockout mice. Thus, dopamine activation is related to the orosensory properties of sucrose and probably to its hedonic value, but that increase is not the equivalent of sucrose reward. In fact, accumbens dopamine may not be necessary for the expression of sucrose preference, but it does track the hedonic value underlying the behavior. If true, this assertion does not apply just to sucrose or even to gustatory stimuli but probably to rewards in general (Wightman, R. M. and Robinson, D. L., 2002). Normal biological rewards are elicited by external events, consummatory stimuli, of which sucrose is a prime exemplar (Craig, W., 1918). The reward value, however, is not determined by the stimulus, but depends on the immediate and remembered circumstances of the animal. The hedonic valence is then added to the afferent sensory neural activity resulting from the stimulus somewhere between the peripheral receptors and behavior. Determining how this comes about remains a central goal of neuroscience.

Glossary

flavor A sensation produced by the combination of the taste, smell, and texture of food. *reward* A stimulus such as food for which an animal will work (see Rolls, E. T., 2005a).

sensory-specific satiety A reduction in the pleasantness of and appetite for a food that has been eaten to satiety in a meal which is partly specific to the food eaten in a meal.

umami The fifth taste, produced by the stimuli monosodium glutamate and 5′-ribonucleotides such as inosine monophosphate and guanosine monophosphate.

4.26.1 Taste Processing in the Primate Cortex

4.26.1.1 Pathways

A diagram of the taste and related olfactory, somatosensory, and visual pathways in primates is shown in Figure 1. Of particular interest is that in primates there is a direct projection from the rostral part of the nucleus of the solitary tract (NTS) to the taste thalamus and thus to the primary taste cortex in the frontal operculum and adjoining insula, with no pontine taste area and associated subcortical projections as in rodents (Norgren, R., 1984; Pritchard, T. C. *et al.*, 1986).This emphasis on cortical processing of taste in primates may be related to the great development of the cerebral cortex in primates, and the advantage of using extensive and similar cortical analysis of inputs from every sensory modality before the analyzed representations from each modality are brought together in multimodal regions to form representations of flavor.

4.26.1.2 The Primary and Secondary Taste Cortex

The primary taste cortex is in the rostral insula and adjacent frontal operculum (Pritchard, T. C. *et al.*, 1986). A secondary cortical taste area in primates was discovered by Rolls E. T. *et al.* (1990) in the caudolateral orbitofrontal cortex, extending several millimeters in front of the primary taste cortex, and also extending to more medial parts of the orbitofrontal cortex (Rolls, E. T. and Baylis, L. L., 1994).

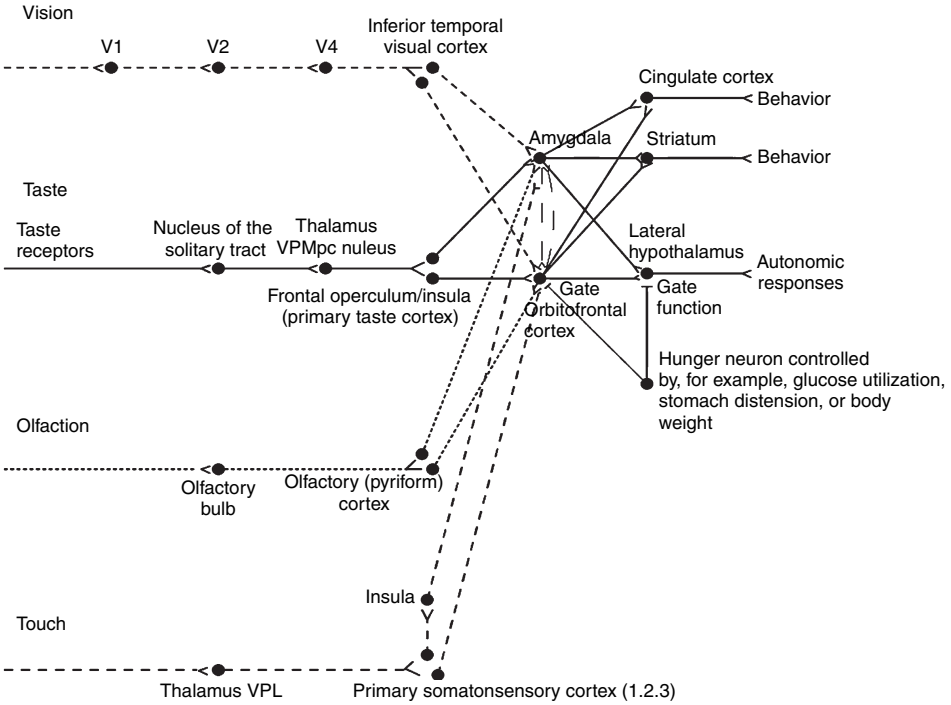

Figure 1 Schematic diagram of the taste and olfactory pathways in primates showing how they converge with each other and with visual pathways. The gate functions shown refer to the finding that the responses of taste neurons in the orbitofrontal cortex and the lateral hypothalamus are modulated by hunger. VPMpc, ventralposteromedial thalamic nucleus; V1, V2, V4, visual cortical areas.

4.26.1.3 Five Prototypical Tastes, Including Umami

In the primary and secondary taste cortex, there are many neurons that respond best to each of the four classical prototypical tastes sweet, salt, bitter and sour (Scott, T. R. *et al.*, 1986; Yaxley, S. *et al.*, 1988; Rolls, E. T. *et al.*, 1990; Rolls, E. T., 1997; Rolls, E. T. and Scott, T. R., 2003), but also there are many neurons that respond best to umami tastants such as glutamate (which is present in many natural foods such as tomatoes, mushrooms and milk; Baylis, L. L. and Rolls, E. T., 1991) and inosine monophosphate (which is present in meat and some fish such as tuna; Rolls, E. T. *et al.*, 1996a).

4.26.2 The Pleasantness of the Taste of Food

The modulation of the reward value of a sensory stimulus such as the taste of food by motivational state, for example hunger, is one important way in which motivational behavior is controlled (Rolls, E. T., 2005a). The subjective correlate of this modulation is that food tastes pleasant when hungry, and tastes hedonically neutral when it has been eaten to satiety. We have found that the modulation of taste-evoked signals by motivation is not a property found in early stages of the primate gustatory system including the nucleus of the solitary tract (Yaxley, S. *et al.*, 1985) and the primary taste cortex (frontal opercular, Rolls, E. T. *et al.*, 1988; insular, Yaxley, S. *et al.*, 1988). In contrast, in the secondary taste cortex, in the caudolateral part of the orbitofrontal cortex, the responses of neurons to the taste of glucose decreases to zero while the monkey is fed glucose to satiety (Rolls, E. T. *et al.*, 1989). It is an important principle that the identity of a taste, and its intensity, are represented separately (in the primary taste cortex) from its pleasantness (in the secondary taste cortex) (Rolls, E. T., 2005a). Thus it is possible to represent what a taste is, and to learn about it, even when we are not hungry.

4.26.3 The Representation of Flavor: Convergence of Olfactory and Taste Inputs

Neuronal responses in the primate primary taste cortex are not driven by olfactory inputs during normal taste/smell tests (Verhagen, J. V. *et al.*, 2004).

However, we found (Rolls, E. T. and Baylis, L. L., 1994) that in the orbitofrontal cortex taste areas, of 112 single neurons which responded to any of these modalities, many were unimodal (taste 34%, olfactory 13%, visual 21%), but were found in close proximity to each other. Some single neurons showed convergence, responding for example to taste and visual inputs (13%), taste and olfactory inputs (13%), and olfactory and visual inputs (5%). Some of these multimodal single neurons had corresponding sensitivities in the two modalities, in that they responded best to sweet tastes (e.g., 1M glucose), and responded more in a visual discrimination task to the visual stimulus which signified sweet fruit juice than to that which signified saline; or responded to sweet taste, and in an olfactory discrimination task to fruit odor (see Figure 2). The different types of neurons (unimodal in different modalities, and multimodal) were frequently found close to one another in tracks made into this region, consistent with the hypothesis that the multimodal representations are actually being formed from unimodal inputs to this region.

It thus appears to be in these orbitofrontal cortex areas that flavor representations are built, where flavor is taken to mean a representation which is evoked best by a combination of gustatory and olfactory input.

The primate amygdala has neurons that combine representations of taste and oral texture (Kadohisa, M. *et al.*, 2005b), and visual stimuli (Wilson, F. A. W. and Rolls, E. T., 2005), and olfactory inputs also reach the amygdala, but less is known about olfactory-taste association learning in the primate amygdala.

4.26.4 The Rules Underlying the Formation of Flavor Representations in the Primate Cortex

Critchley H. D. and Rolls E. T. (1996c) showed that 35% of orbitofrontal cortex olfactory neurons categorized odors based on their taste association in an olfactory-to-taste discrimination task. Rolls E. T. *et al.* (1996a) found that 68% of orbitofrontal cortex odor-responsive neurons modified their responses in some way following changes in the taste reward associations of the odorants during olfactory-taste discrimination learning and its reversal. (In an olfactory discrimination experiment, if a lick response to one odor, the S+, is made a drop of glucose taste reward is obtained; if incorrectly a lick response is made to another odor, the S−, a drop of aversive saline is obtained. At some time in the experiment, the contingency between the odor and the taste is reversed, and when the meaning of the two odors alters, so does the behavior. It is of interest to investigate in which parts of the olfactory system the neurons show reversal, for where they do, it can be concluded that the neuronal response to the odor depends on the taste with which it is associated, and does not depend primarily on the physicochemical structure of the odor). An example of a neuron showing olfactory-to-taste reversal is shown in Figure 3. These findings demonstrate directly a coding principle in primate olfaction whereby the responses of some orbitofrontal cortex olfactory neurons are modified by and depend upon the taste with which the

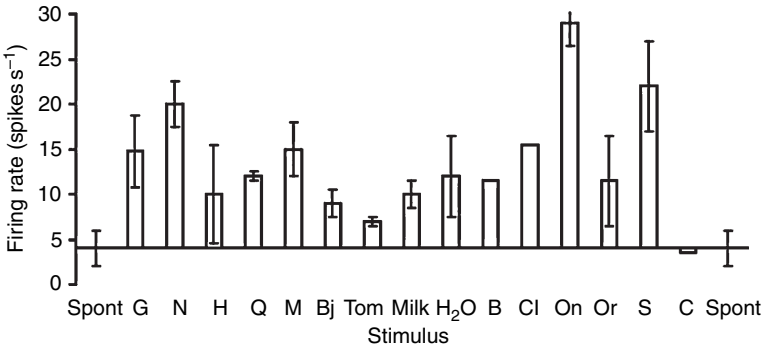

Figure 2 Olfactory to taste convergence on to a single neuron in the macaque orbitofrontal cortex. Spont, spontaneous; G, 1 M glucose; N, 0.1 M NaCl; H, 0.01 M hycrochloride; Q, 0.001 M quinine hycrochloride; M, 0.1 M monosodium glutamate; Bj, 20% blackcurrant juice; Tom, tomato juice; B, banana odor; Cl, clove oil odor; On, onion odor; Or, orange odor; S, salmon odor; C, control no-odor presentation. The mean responses ± standard error of the means are shown. The neuron responded best to the savory tastes of NaCl and monosodium glutamate and to the consonant odors of onion and salmon. Adapted from Rolls, E. T. and Baylis, L. L. 1994. Gustatory, olfactory, and visual convergence within the primate orbitofrontal cortex. J. Neurosci. 14, 5437–5452.

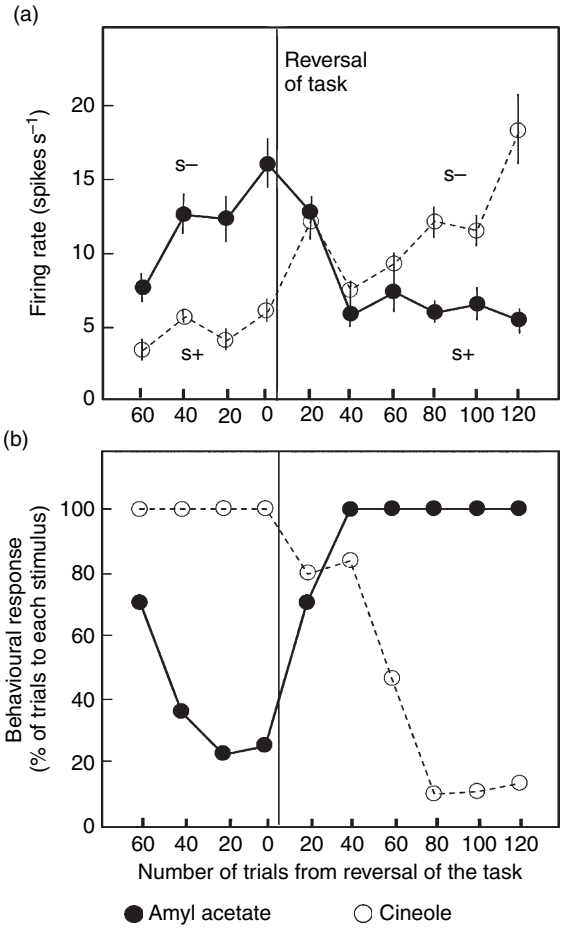

Figure 3 Flavor learning: olfactory to taste association reversal by an orbitofrontal cortex neuron. (a) The activity of a single orbitofrontal olfactory neuron during the performance of a two-odor olfactory discrimination task and its reversal is shown. Each point represents the mean poststimulus activity of the neuron in a 500 ms period on approximately 10 trials of the different odorants. The standard errors of these responses are shown. The odorants were amyl acetate (closed circle; initially s–) and cineole (open circles; initially s+). After 80 trials of the task the reward associations of the stimuli were reversed. This neuron reversed its responses to the odorants following the task reversal. (b) The behavioral responses of the monkey during the performance of the olfactory discrimination task. The number of lick responses to each odorant is plotted as a percentage of the number of trials to that odorant in a block of 20 trials of the task. Adapted from Rolls, E. T., Critchley, H., Mason, R., and Wakeman, E. A. 1996. Orbitofrontal cortex neurons: role in olfactory and visual association learning. J. Neurophysiol. 75, 1970–1981.

odor is associated (Rolls, E. T., 2001; 2002a; 2002b; Deco, G. and Rolls, E. T., 2005b).

Some neurons in the same orbitofrontal cortex region are influenced by the sight as well as by the taste of food, and this is a learned convergence (Thorpe, S. J. *et al.*, 1983; Rolls, E. T. *et al.*, 1996b). As a result of this learning, food choice based on the visual–taste association can be made, and potentially the sight of food can influence its perceived taste. It is of interest that the olfactory-taste association learning is less complete, and much slower, than the modifications found for orbitofrontal visual neurons during visual–taste learning and its reversal (Rolls, E. T. *et al.*, 1996b). This relative inflexibility of olfactory responses is consistent with the need for some stability in odor–taste associations to facilitate the formation and perception of flavors.

Some orbitofrontal cortex olfactory neurons do not code in relation to the taste with which the odor is associated (Critchley, H. D. and Rolls, E. T., 1996c) so that there is also a taste-independent representation of odor in this region.

4.26.5 The Responses of Orbitofrontal Cortex Taste and Olfactory Neurons to the Texture, and Temperature of Food

The texture of food may be considered as a component of the flavor of food. The texture of food, including its viscosity, influences some neurons in the primary taste cortex that have taste responses (Verhagen, J. V. *et al.*, 2004). These texture inputs also thereby influence neurons in the primate orbitofrontal cortex (Rolls, E. T. *et al.*, 2003b), which thus becomes a region where flavor representations can be influenced by the taste, smell, sight and texture of food. Some of the orbitofrontal cortex neurons with texture-related responses encode parametrically the viscosity of food in the mouth (shown using a methyl cellulose series in the range 1–10 000 centiPoise) (see Figure 3), and others independently encode the particulate quality of food in the mouth, produced quantitatively for example by adding 20–100 μm microspheres to methyl cellulose (Rolls, E. T. *et al.*, 2003b). Other neurons respond to water, and others to the somatosensory stimuli astringency as exemplified by tannic acid (Critchley, H. D. and Rolls, E. T., 1996a), and to capsaicin (Rolls, E. T. *et al.*, 2003b; Kadohisa, M. *et al.*, 2004; 2005a).

Texture in the mouth is an important indicator of whether fat is present in a food, which is important not only as a high value energy source, but also as a potential source of essential fatty acids. In the orbitofrontal cortex, Rolls E. T. *et al.* (1999) have found a

population of neurons that responds when fat is in the mouth. The fat-related responses of these neurons are produced at least in part by the texture of the food rather than by chemical receptors sensitive to certain chemicals, in that such neurons typically respond not only to foods such as cream and milk containing fat, but also to paraffin oil (which is a pure hydrocarbon) and to silicone oil ($Si(CH_3)O_2)_n$). Moreover, the texture channel through which these fat-sensitive neurons are activated are separate from viscosity sensitive channels, in that the responses of these neurons cannot be predicted by the viscosity of the oral stimuli (Verhagen, J. V. *et al.*, 2003). Some of the fat-related neurons do though have convergent inputs from the chemical senses, in that in addition to taste inputs, some of these neurons respond to the odor associated with a fat, such as the odor of cream (Rolls, E. T. *et al.*, 1999). Feeding to satiety with fat (e.g., cream) decreases the responses of these neurons to zero on the food eaten to satiety, but if the neuron receives a taste input from for example glucose taste, that is not decreased by feeding to satiety with cream. Thus there is a representation of the macronutrient fat in this brain area, and the activation produced by fat is reduced by eating fat to satiety.

In addition, we have shown recently (Kadohisa, M. *et al.*, 2004; 2005a) that some neurons in the orbitofrontal cortex reflect the temperature of substances in the mouth, and that this temperature information is represented independently of other sensory inputs by some neurons, and in combination with taste or texture by other neurons.

4.26.6 The Representation of the Pleasantness of Flavor in the Brain: Olfactory and Visual Sensory-Specific Satiety, and Their Representation in the Primate Orbitofrontal Cortex

In the orbitofrontal cortex, it is found that the decreases in the responsiveness of the neurons are relatively specific to the food with which the monkey has been fed to satiety. For example, in seven experiments in which the monkey was fed glucose solution, neuronal responsiveness decreased to the taste of the glucose but not to the taste of blackcurrant juice. Conversely, in two experiments in which the monkey was fed to satiety with fruit juice, the responses of the neurons decreased to fruit juice but not to glucose (Rolls, E. T. *et al.*, 1989).

It has also been possible to investigate whether the olfactory representation in the orbitofrontal cortex is affected by hunger, and thus whether the pleasantness of odor is represented in the orbitofrontal cortex. In satiety experiments, Critchley H. D. and Rolls E. T. (1996b) showed that the responses of some olfactory neurons to a food odor are decreased during feeding to satiety with a food (e.g., fruit juice) containing that odor. In particular, seven of nine olfactory neurons that were responsive to the odors of foods, such as blackcurrant juice, were found to decrease their responses to the odor of the satiating food. The decrease was typically at least partly specific to the odor of the food that had been eaten to satiety, potentially providing part of the basis for sensory-specific satiety. It was also found for eight of nine neurons that had selective responses to the sight of food that they demonstrated a sensory-specific reduction in their visual responses to foods following satiation. These findings show that the olfactory and visual representations of food, as well as the taste representation of food, in the primate orbitofrontal cortex are modulated by hunger. Usually a component related to sensory-specific satiety can be demonstrated. It is thus the orbitofrontal cortex which computes sensory-specific satiety, and it is in areas such as this and the areas that receive from it that neuronal activity may be related to whether a food tastes pleasant, and to whether the food should be eaten (see Scott, T. R. *et al.*, 1995; Critchley, H. D. and Rolls, E. T., 1996c; Rolls, E. T. and Rolls, J. H., 1997; Rolls, E. T., 1999; 2000a; 2000b; Rolls, E. T. and Scott, T. R., 2003; Rolls, E. T., 2005a; 2005b; 2006).

The enhanced eating when a variety of foods is available, as a result of the operation of sensory-specific satiety, may have been advantageous in evolution in ensuring that different foods with important different nutrients were consumed, but today in humans, when a wide variety of foods is readily available, it may be a factor that can lead to overeating and obesity (Rolls, E. T., 2005a).

4.26.7 Functional Neuroimaging Studies in Humans

4.26.7.1 Taste

In humans it has been shown in neuroimaging studies using functional magnetic resonance imaging (fMRI) that taste activates an area of the anterior insula/frontal operculum, which is probably the primary

taste cortex, and part of the orbitofrontal cortex, which is probably the secondary taste cortex (Francis, S. *et al.*, 1999; Small, D. M. *et al.*, 1999; O'Doherty, J. *et al.*, 2001; de Araujo, I. E. T. *et al.*, 2003b; Faurion, A. *et al.*, 2005). Another study has recently shown that umami taste stimuli, including monosodium glutamate, activate similar cortical regions of the human taste system to those activated by a prototypical taste stimulus, glucose (de Araujo, I. E. T. *et al.*, 2003a). A part of the rostral anterior cingulate cortex (ACC) was also activated in this study, as it is in many studies by taste, odor, flavor, and oral texture (Rolls, E. T., 2007). O'Doherty J. *et al.* (2001) showed that the human amygdala was as much activated by the affectively pleasant taste of glucose as by the affectively negative taste of NaCl, and thus provided evidence that the human amygdala is not especially involved in processing aversive as compared to rewarding stimuli.

4.26.7.2 Odor

In humans, in addition to activation of the pyriform (olfactory) cortex (Zald, D. H. and Pardo, J. V., 1997; Sobel, N. *et al.*, 2000; Poellinger, A. *et al.*, 2001), there is strong and consistent activation of the orbitofrontal cortex by olfactory stimuli (Zatorre, R. J. *et al.*, 1992; Francis, S. *et al.*, 1999). In an investigation of where the pleasantness of olfactory stimuli might be represented in humans, O'Doherty J. *et al* (2000) showed that the activation of an area of the orbitofrontal cortex to banana odor was decreased (relative to a control vanilla odor) after bananas were eaten to satiety. Thus activity in a part of the human orbitofrontal cortex olfactory area is related to sensory-specific satiety, and this is one brain region where the pleasantness of odor is represented. Flavor sensory-specific satiety is also represented in the human orbitofrontal cortex, in that when a whole food (either chocolate milk, or tomato juice) is eaten to satiety activation to the flavor of the food eaten to satiety, but not to the other flavor, decreases in the orbitofrontal cortex but not in the primary taste cortex (Kringelbach, M. L. *et al.*, 2003; see Figure 4).

An important issue is whether there are separate regions of the brain discriminable with fMRI that represent pleasant and unpleasant odors. To investigate this, we measured the brain activations produced by three pleasant and three unpleasant odors. The pleasant odors chosen were linalyl acetate (floral, sweet), geranyl acetate (floral), and alpha-ionone (woody, slightly food-related). (Chiral substances were used as racemates.) The unpleasant odors chosen were hexanoic acid, octanol, and isovaleric acid. We found that they activated dissociable parts of the human brain (Rolls, E. T. *et al.*, 2003a). Pleasant but not unpleasant odors were found to activate a medial region of the rostral orbitofrontal cortex. Further, there was a correlation between the subjective pleasantness ratings of the six odors given during the investigation with activation of a medial region of the rostral orbitofrontal cortex. In contrast, a correlation between the subjective unpleasantness ratings of the six odors was found in regions of the left and more lateral orbitofrontal cortex. Activation was also found in the ACC, with a middle part of the anterior cingulate activated by both pleasant and unpleasant odors, and a more anterior part of the ACC showing a correlation with the subjective pleasantness ratings of the odors. Activation in primary olfactory cortical areas was not correlated with the pleasantness of the odor, but was correlated with the intensity (Rolls, E. T. *et al.*, 2003a).

4.26.7.3 Olfactory-Taste Convergence to Represent Flavor

To investigate where in the human brain interactions between taste and odor stimuli may be realized to implement flavor, we performed an event-related fMRI study with sucrose and monosodium glutamate taste, and strawberry and methional (chicken) odors, delivered unimodally or in different combinations (de Araujo, I. E. T. *et al.*, 2003c). The brain regions that were activated by both taste and smell included parts of the caudal orbitofrontal cortex, amygdala, insular cortex and adjoining areas, and ACC. It was shown that a small part of the anterior (putatively agranular) insula responds to unimodal taste and to unimodal olfactory stimuli; and that a part of the anterior frontal operculum is a unimodal taste area (putatively primary taste cortex) not activated by olfactory stimuli. Activations to combined olfactory and taste stimuli where there was little or no activation to either alone (providing positive evidence for interactions between the olfactory and taste inputs) were found in a lateral anterior part of the orbitofrontal cortex. Correlations with consonance ratings for the smell and taste combinations, and for their pleasantness, were found in a medial anterior part of the orbitofrontal cortex (see Figure 5). These results provide evidence on the neural substrate for the convergence of taste and olfactory stimuli to produce flavor in humans, and where the pleasantness of flavor is represented in the human brain (de Araujo, I. E. T. *et al.*, 2003c).

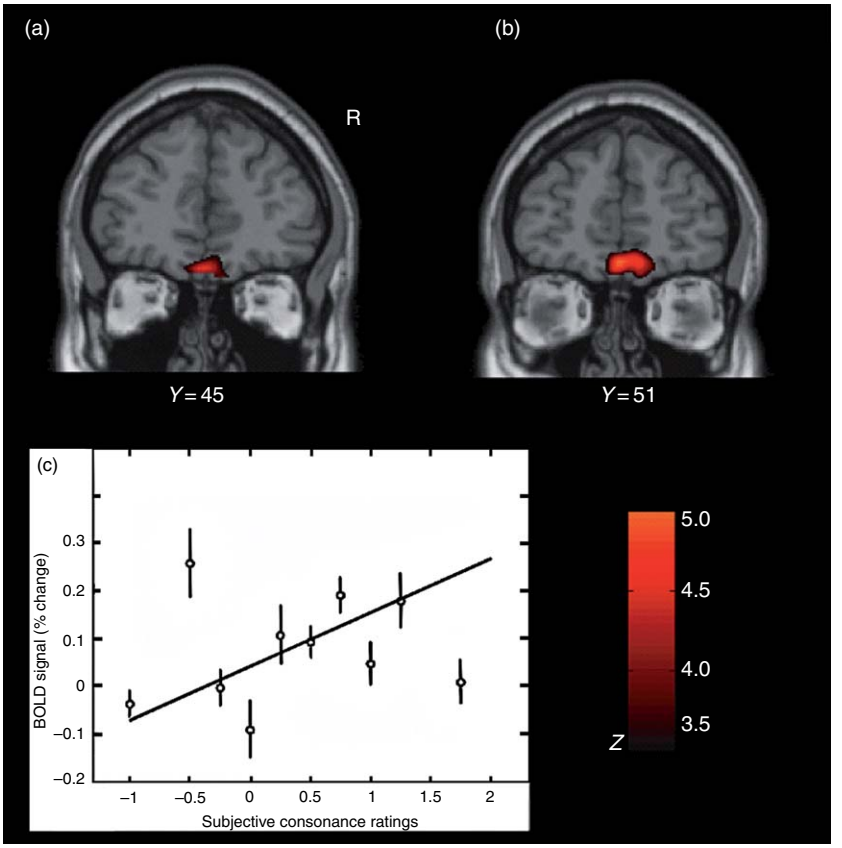

Figure 4 Flavor formation in the human brain, shown by cross-modal olfactory–taste convergence. Brain areas where activations were correlated with the subjective ratings for stimulus (taste–odor) consonance and pleasantness. (a) A second-level, random effects analysis based on individual contrasts (the consonance ratings being the only effect of interest) revealed a significant activation in a medial part of the anterior orbitofrontal cortex. (b) Random effects analysis based on the pleasantness ratings showed a significant cluster of activation located in a (nearby) medial part of the anterior orbitofrontal cortex. The images were thresholded at $P < 0.0001$ for illustration. (c) The relation between the blood oxygen level-dependent (BOLD) signal from the cluster of voxels in the medial orbitofrontal cortex shown in (a) and the subjective consonance ratings. The analyses shown included all the stimuli included in this investigation. The means and standard errors of the mean across subjects are shown, together with the regression line, for which $r = 0.52$. Adapted from de Araujo, I. E. T., Rolls, E. T., Kringelbach, M. L., McGlone, F., and Phillips, N. 2003c. Taste-olfactory convergence, and the representation of the pleasantness of flavour, in the human brain. Eur. J. Neurosci. 18, 2374–2390.

We have also investigated how the flavor of savory foods is produced. Umami taste is produced by glutamate acting on a fifth taste system. However, glutamate presented alone as a taste stimulus is not highly pleasant, and does not act synergistically with other tastes (sweet, salt, bitter and sour). McCabe C. and Rolls E. T. (2007) showed that when glutamate is given in combination with a consonant, savory, odor (vegetable), the resulting flavor can be much more pleasant. Moreover, we showed using functional brain imaging with fMRI that the glutamate and savory odor combination produced much greater activation of the medial orbitofrontal cortex and pregenual cingulate cortex than the sum of the activations by the taste and olfactory components presented separately. Supralinear effects were much less (and significantly less) evident for sodium chloride and vegetable odor. Further, activations in these brain regions were correlated with the pleasantness, consonance of the taste and olfactory components, and the fullness of the flavor, of the stimuli. We thus proposed that glutamate acts by the nonlinear effects it can produce when combined with a consonant odor (McCabe, C. and Rolls, E. T., 2007). I therefore propose the concept that umami can be thought of as a rich and delicious flavor that is produced by a combination of glutamate taste and a consonant savory odor. Glutamate is thus a flavor enhancer because of the way that it can combine supralinearly with consonant odors.

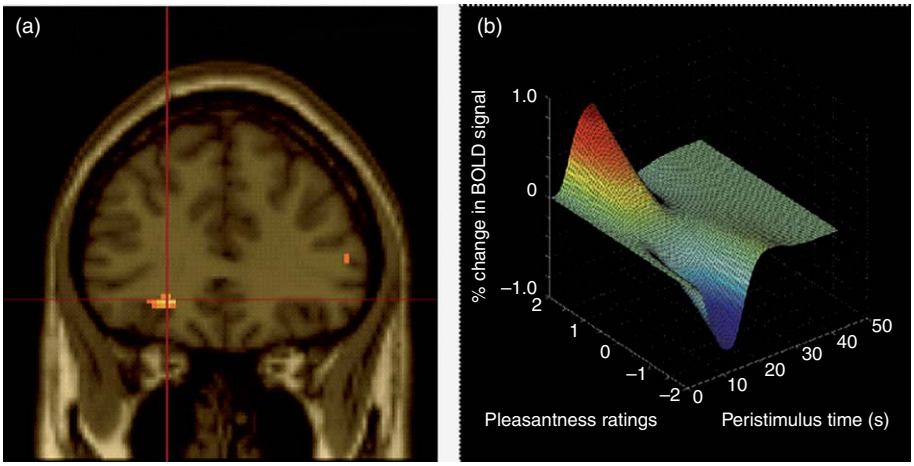

Figure 5 Areas of the human orbitofrontal cortex with activations correlating with pleasantness ratings for flavor in a sensory-specific satiety design. (a) Coronal section through the region of the orbitofrontal cortex from the random effects group analysis showing the peak in the left orbitofrontal cortex (Talairach co-ordinates *X, Y, Z* = −22, 34, −8, z-score = 4.06), in which the blood oxygen level-dependent (BOLD) signal in the voxels shown in yellow was significantly correlated with the subjects' subjective pleasantness ratings of the foods throughout an experiment in which the subjects were hungry and found the food pleasant, and were then fed to satiety with the food, after which the pleasantness of the food decreased to neutral or slightly unpleasant. The design was a sensory-specific satiety design, and the pleasantness of the food not eaten in the meal, and the BOLD activation in the orbitofrontal cortex, were not altered by eating the other food to satiety. The two foods were tomato juice and chocolate milk. (b) Plot of the magnitude of the fitted hemodynamic response from a representative single subject against the subjective pleasantness ratings (on a scale from −2 to +2) and peristimulus time in seconds. Adapted from Kringelbach, M. L., O'Doherty, J., Rolls, E. T., and Andrews, C. 2003. Activation of the human orbitofrontal cortex to a liquid food stimulus is correlated with its subjective pleasantness. Cereb. Cortex 13, 1064–1071.

4.26.7.4 Cognitive Influences on Olfactory and Flavor Processing

In line with the neuronal convergence of visual and taste inputs on to single neurons in the orbitofrontal cortex (see above), it is found that the sight of food can influence its perceived flavor, and an fMRI correlate of this has been reported (Osterbauer, R. A. *et al.*, 2005). An example of this interaction is that if a white wine is colored red, then adjectives used to describe the flavor of red wine are used to describe the flavor of the white wine.

To investigate how cognitive this influence could be, de Araujo I. E. T. *et al.* (2005) delivered a standard test odor (isovaleric acid with added cheese flavor), but paired it on some trials with a (visually presented) word label Cheddar cheese, and on other trials with the word label body odor. It was found that the word label produced a large modulation of the olfactory activation in the secondary olfactory cortex in the orbitofrontal cortex (with also some modulation in the amygdala). Moreover, the activations in the orbitofrontal cortex were correlated with the pleasantness ratings given by the subjects of the test odor, which were influenced by the word label. In a control with clean air from the olfactometer, the word labels had much less influence, so that their effect was in particular to modulate the activations being produced in the secondary olfactory cortex by an olfactory stimulus. Thus cognitive influences from the linguistic level, the level of words, can reach down into the secondary olfactory cortex in the orbitofrontal cortex, and modulate their representation of olfactory stimuli (de Araujo, I. E. T. *et al.*, 2005). The mechanism is probably similar to the way in which top-down attentional processes operate, that is by a biased competition mechanism (Rolls, E. T. and Deco, G., 2002; Deco, G. and Rolls, E. T., 2003; 2004; 2005a; 2005c).

It is thus becoming possible to start to understand not only where flavor is represented in the brain, but also how the affective value of smell, taste and flavor are represented, how these representations are influenced by visual stimuli and cognitive states, and how these representations fit into a wider picture of the brain processes underlying the affective or hedonic value of stimuli. This in turn helps to advance understanding of the neural basis of appetite, the control of food intake, and emotion, and their disorders (Rolls, E. T., 2005a).

4.27.1 Introduction

Demographic shifts in the global population are occurring rapidly with escalation in both the number and the percentage of elderly persons (Cohen, J. E., 2003; Administration on Aging, 2004). Over 400 million people worldwide are currently 65 years of age or greater (Davies, A. M., 1989; Cohen, J. E., 2003), and this number is expected to exceed 1.5 billion by 2050 (Cohen, J. E., 2003). A significant proportion of this population will have taste impairments that can potentially alter the health and well-being of the elderly. While disorders of taste can occur throughout the lifespan, they are far more prevalent in an older population. Diagnostic terms for taste disorders include ageusia (absence of taste), hypogeusia (diminished sensitivity of taste), and dysgeusia (distortion of normal taste). Research studies and clinical reports indicate that hypogeusia and dysgeusia commonly occur in older individuals (Schiffman, S. S., 1993; 1997) while ageusia is relatively rare (Pribitkin, E. *et al*., 2003). The aim of this chapter is to provide an overview of gustatory perception in older individuals. Topics to be covered include changes of taste perception at thresholds levels, changes of taste perception at suprathreshold levels, medications and medical conditions associated with taste alterations, as well as taste losses in the absence of drugs and disease.

An intact sense of taste is vital for persons of all ages. Taste is a phylogenetically primitive sense that serves both as a precautionary mechanism and as the initial internal analyzer for materials ingested into the oral cavity. It enables us to distinguish between nutritive chemicals (such as sugars) and potentially harmful compounds (such as bitter toxic alkaloids).

Failure to detect the bitter taste warning from alkaloid poisons at the gateway to the stomach and intestines can have deadly consequences. Overall, taste sensations serve as a quality check for the identity and safety of food in the mouth (i.e., should we swallow the contents in our mouths or spit them out?). In addition to their role in identity and safety, taste sensations (along with smell and trigeminal sensations) contribute to the digestion of food by triggering salivary, gastric, pancreatic, and intestinal secretions that prepare the body for the absorption of nutrients (Giduck, S. A. *et al.*, 1987; Schiffman, S. S., and Warwick, Z. S., 1992; Teff, K. L. and Engelman, K., 1996). Gustatory signals additionally serve as indicators of the nutritional value of a food from a learned association of the food's taste with its postingestive effects (Warwick, Z. S. and Schiffman, S. S., 1991; Drewnowski, A. *et al.*, 1995; Stubbs, R. J. and Whybrow, S., 2004). This learned association of taste signals with metabolic consequences enables food intake and meal size to be modulated in anticipation of nutritional needs. Thus, alterations in the ability to taste are not merely an inconvenience but rather can impact survival, general health, and quality of life.

The qualitative range of taste has not been fully established. Traditionally, much taste research has presumed the existence of only four (or possibly five) independent taste qualities, the four so-called basic or primary tastes (sweet, sour, salty, and bitter) and a fifth quality, the taste of glutamate salts called umami. However, data are accumulating that suggest other sensory qualities such as fatty (Gilbertson, T. A. *et al.*, 1997), metallic (Schiffman, S. S., 2000), starchy/polysaccharide (Sclafani, A., 2004), chalky (Schiffman, S. S., and Erickson, R. P., 1993), and astringent (Schiffman, S. S., *et al.*, 1992) are carried by taste nerves. Thus, while the terms sweet, sour, salty, and bitter may be familiar and have linguistic relevance, they do not describe the entire range of tastes perceived by humans and other animals.

The ability to perceive the taste signals of specific sensory qualities (such as salty or sweet) are especially important for subgroups of the elderly population such as those with hypertension who must comply with salt-restricted diets or those with diabetes who must reduce their consumption of sugar (Schiffman, S. S., 1997). Reduced sensitivity to the oral component of fats in the elderly can increase their risk of cardiovascular disease, diabetes, hypertension, and other conditions in which high fat intake is contraindicated. Taste losses along with other physiological and psychological factors also contribute to the observed decline in food intake in many older persons (Morley, J. E., 2001). Overall, taste disorders that impair or distort the taste of palatable as well as unpalatable substances can increase the risk of numerous adverse safety and health-related issues for an elderly population.

4.27.2 Changes of Taste at Threshold Levels

4.27.2.1 Taste Thresholds in a General Elderly Population

An overview of research studies indicates that the detection threshold (DT) and recognition threshold (RT) for simple basic tastes (sweet, sour, salty, and bitter) are moderately elevated in older persons compared to a younger cohort (e.g., Richter, C. P. and Campbell, K. H., 1940; Harris, H. and Kalmus, H., 1949; Bourlière, F. *et al.*, 1958; Hinchcliff, R. 1958; Cooper, R. M. *et al.*, 1959; Kalmus, H. and Trotter, W. R., 1962; Glanville, E. V. *et al.*, 1964; Smith, S. E. and Davies, P. D., 1973; Grzegorczyk, P. B. *et al.*, 1979; Murphy, C., 1979; Schiffman, S.S. *et al.*, 1979; Dye, C. J. and Koziatek, D. A., 1981; Schiffman, S. S. *et al.*, 1981; Moore, L. M. *et al.*, 1982; Weiffenbach, J. M. *et al.*, 1982; Schiffman, S. S. *et al.*, 1990; 1991; Schiffman, S. S., 1993; Schiffman, S. S. *et al.*, 1994; Stevens, J. C. *et al.*, 1995; Stevens, J. C., 1996; Stevens J. C. and Traverzo, A., 1997; Schiffman, S. S. *et al.*, 1998; Mojet, J. *et al.*, 2001; Yamauchi, Y. *et al.*, 2002; Fukunaga, A. *et al.*, 2005). An elevated DT indicates that the elderly require the presence of more molecules (or ions) for a sensation to be perceived compared to younger persons – that is, the elderly have reduced absolute sensitivity. An elevated RT signifies that a greater concentration of a tastant is required before it can be correctly identified. Furthermore, thresholds are higher for a compound in a mixture than in a simple aqueous solution (Stevens, J. C. and Traverzo, A., 1997), that is, other ingredients in a mixture can mask significant food components such as NaCl, making it harder to detect and recognize salt in food than alone in a simple aqueous solution.

Tables 1–9 show the results of studies that compare mean thresholds for the elderly with those of the young for a range of compounds including sodium salts with different anions (Schiffman, S. S. *et al.*, 1990), bitter compounds (Schiffman, S. S. *et al.*, 1994), sweeteners (Schiffman, S. S. *et al.*, 1981), acids

[a] Logarithm of the 1-octanol/water partition coefficient.
Data are from Schiffman, S. S., Gatlin, L. A., Frey, A. E., Heiman, S. A., Stagner, W. C., and Cooper, D. C. 1994. Taste perception of bitter compounds in young and elderly persons: relation to lipophilicity of bitter compounds. Neurobiol. Aging 15, 743–750.

(Schiffman, S. S., 1993), astringent compounds (Schiffman, S. S. *et al.*, 1989), amino acids (Schiffman, S. S. *et al.*, 1979) including glutamate salts (Schiffman, S. S. *et al.*, 1991), fats (Schiffman, S. S., *et al.*, 1998), and gums (Schiffman, S. S. *et al.*, 1989). The subjects in these studies were elderly individuals who took an average of 3.4 medications but who otherwise led active, normal lives. For DTs, the ratio of DT (elderly)/DT (young) revealed that DTs in the elderly were higher by the following amounts: 11.6 times higher for sodium salts; 2.7 times higher for sweeteners; 4.3 times higher for acids; 2.8 for astringent compounds; 7.0 times higher for bitter compounds; 2.5 times higher for amino acids; 5.0 times higher for glutamate salts; 3.1 times higher for fats/oils; and 3.7 times higher for polysaccharides/gums. The average loss in detection across this qualitative range of compounds is 4.74. However, the degree of loss within a group (such as sodium salts) was not uniform but rather varied with the chemical structure of the compounds tested. For RTs, the ratio of RT (elderly)/RT (young) revealed that RTs in the elderly were higher by the following amounts: 5.8 times higher for sodium salts; 2.1 times higher for sweeteners; 6.8 times higher for acids with sour tastes; 3.0 for astringent compounds; 7.5 times higher for bitter compounds; and 3.0 times higher for polysaccharides/gums. The average loss in recognition across these taste qualities is 4.7.

4.27.2.1.1 Sodium salts

Table 1 compares the taste DTs and RTs for 10 sodium salts in young and elderly persons (see Schiffman, S. S. *et al.*, 1990). The DTs of these salts were highly correlated with the molar conductivity of the anion. Molar conductivity (λ) is a measure of the electrical charge carried by the anion per unit time. Furthermore, age-related decrements as determined by the ratio DT (elderly)/DT (young) were greatest for anions with the largest molar conductivity (Na sulfate, Na tartrate, Na citrate, and Na succinate). That is, age-related losses in sensitivity

to sodium salts were greatest for anions with the highest charge mobility. RTs are also given in Table 1 for those subjects who did perceive saltiness; however, some subjects did not recognize a salty component for some of these sodium salts at concentrations 64 times higher than the DT.

Table 6 Mean detection thresholds for amino acids in elderly and young subjects

Stimulus	*Elderly (E)*	*Young (Y)*	*E/Y*
L-Alanine	19.5 mM	16.2 mM	1.20

L-Threonine	0.020 M	0.0257 M	0.78
L-Tryptophan	2.88 mM	2.29 mM	1.26
L-Valine	0.0115 M	0.00416 M	2.76

Data are from Schiffman, S. S., Hornack, K., and Reilly, D. 1979. Increased taste thresholds of amino acids with age. Am. J. Clin. Nutr. 32, 1622–1627.

4.27.2.1.2 Bitter compounds

Table 2 compares the DTs and RTs for 12 bitter compounds in young and elderly subjects (see Schiffman, S. S. *et al.*, 1994). Subjects included both tasters and nontasters of the bitter compound phenylthiocarbamide (PTC). A strong relationship between bitter threshold values and the logarithm of the octanol/water partition coefficient ($\log P$) was found for both young and elderly subjects. The logarithm of the 1-octanol/water partition coefficient ($\log P$) is a measure of the lipophilicity of the bitter compound. The greatest losses at the threshold level for the elderly were for the least lipophilic compounds, that is, $MgNO_3$, $MgSO_4$, and KNO_3. There were no differences in DTs or RTs for tasters and nontasters of PTC with the exception of PTC itself.

4.27.2.1.3 Sweet compounds

Table 3 compares the taste DTs and RTs for 11 sweeteners in young and elderly persons. Sweeteners with the highest DTs are natural sugars for both age groups (see Schiffman, S. S. *et al.*, 1981). The fact that high concentrations are needed for the detection of sugars may have had survival value for past generations who needed to choose only the most caloric foods in a natural environment. Sweeteners with the lowest DTs (i.e., low concentrations are

Table 7 Mean detection thresholds for glutamate salts with and without the taste enhancer inosine 5′-monophosphate (IMP) in elderly and young subjects

Stimulus	*Elderly (E)*	*Young (Y)*	*E/Y*

Data from Schiffman, S. S., Rascoe, D., and Garcia, R. A. 1989. The effects of age and race on thresholds and magnitude estimates of edible gums. Chem. Senses 14, 743.

detected) for both age groups were those compounds with the greatest possible sites capable of intermolecular hydrogen bonding with the sweetener taste receptor. The RTs for the large sweetener molecules such as monellin and thaumatin were extremely variable in the elderly, so means are not given.

4.27.2.1.4 Acids

Table 4 compares the DTs and RTs for eight acids with sour tastes in young and elderly persons (Schiffman, S. S., 1993). The loss in sensitivity with age for HCl, the acid with the lowest molecular weight, was significantly greater than losses for the organic acids.

4.27.2.1.5 Astringent compounds

DTs and RTs for six astringent compounds are given in Table 5. DTs for astringent compounds are in the same general range as that for the acids in Table 4. This is most likely due to the fact that all of these astringent compounds have pH values below 3.5 at the concentrations tested. RTs for astringency were up to six times higher than the DTs for astringent compounds in young subjects and four times higher for elderly subjects. Each of these astringent compounds was reported to have sour and bitter tastes that emerged at concentrations intermediate between the DT and RT for astringency. Astringent compounds are found in natural food products and are important sensory components of many beverages such as wine, tea, and fruit juices (Bate-Smith, E. C., 1954; Robichaud, J. L. and Noble, A. C., 1990). Astringency is associated with a drying or a puckering sensation on the tongue and in the oral cavity. A portion of this sensation appears to be transmitted through gustatory nerves because patients with severed trigeminal nerves report drying or puckering sensations on the tongue (the trigeminal nerve innervates the buccal cavity of the mouth and the first 2/3 of the tongue) (Schiffman, S. S., unpublished clinical tests).

4.27.2.1.6 Amino acids

Table 6 compares the taste DTs for 19 L-amino acids and 4 monohydrochloride derivatives in young and elderly persons (see Schiffman, S. S. *et al.*, 1979). The ratio DT (elderly)/DT (young) for 20 of the 23 amino acid compounds was >1, which was highly statistically significant. There were no major differences in the degree of loss with compound type although age-related losses tended to be higher for two amino acids with side chains containing basic groups (L-histidine and L-lysine) and their monohydrochloride derivatives.

4.27.2.1.7 Glutamate salts

Table 7 compares the DTs for five glutamate salts (sodium glutamate, potassium glutamate, ammonium glutamate, calcium diglutamate, and magnesium diglutamate) in young and elderly persons (see Schiffman, S. S. *et al.*, 1991). The effect of inosine 5′-monophosphate (IMP), a taste enhancer, on taste thresholds of glutamate compounds at two concentrations (0.1 and 1.0 mM IMP) was also investigated. While 0.1 mM IMP lowered thresholds for all the five salts in young but not older subjects, 1 mM IMP lowered thresholds in both young and elderly groups.

4.27.2.1.8 Fats (emulsified oils)

Recent data suggest that fats and oils have taste components because sensations from these stimuli can be detected on the lateral posterior sides of the tongue without tongue movement (Schiffman, S. S. *et al.*, 1998), and electrophysiological data indicate that fatty acids activate taste nerves (Gilbertson, T. A. *et al.*, 1997). Table 8 compares the mean DTs for three different oils in four different emulsifiers in young and elderly subjects. The oils were refined, bleached, deodorized soybean oil (long-chain triglyceride, LCT); medium-chain triglyceride (MCT) oil; and light mineral oil. These fats are LCTs, MCTs, and a mixture of liquid hydrocarbons from petroleum, respectively. Oil-in-water emulsions were made with each oil using one of the four different emulsifiers: Polysorbate 80 (Tween® 80), sodium stearoyl lactylate (Emplex), sodium caseinate, and acacia gum. Statistical analysis revealed significant main effects for age (elderly had higher thresholds) and emulsifier. The low DTs of the oils emulsified in acacia gum (which suspends fat globules in a matrix rather than acting as a surfactant) accounted for the main effect of emulsifier. There were no significant differences in the thresholds with or without nose clips. The mean DT of the oils across all conditions for young subjects was 5.30% oil (v/v) while mean DTs for the elderly was 15.8% oil (v/v). The lowest mean DT was obtained for MCT oil in acacia gum for young subjects (2.85%). The highest mean DT was obtained for MCT oil in Emplex for elderly subjects (25.0%).

4.27.2.1.9 Complex polysaccharides/gums

Gums are complex polysaccharides used as thickening and gelling agents in many foods such as mayonnaise, ice cream, syrups, cheese, and dietetic foods (Klose, R. E. and Glicksman, M., 1972). A portion of the oral sensation from polysaccharides in humans is transmitted through gustatory nerves because patients with severed trigeminal nerves can differentiate between water alone and gums in water when dropped on the tongue (Schiffman, S. S., unpublished clinical tests). Animal data also suggest that polysaccharides may have a taste (Sclafani, A. 2004). DTs and RTs for gums commonly added to foods are given in Table 9 (from Schiffman, S. S. *et al.* 1989). The ratio of DT (elderly)/DT (young) varied with the gum structure from 1.58 for acacia gum to 7.05 for locust bean gum. On the descriptor scales, subjects not only commented on the thickness but also used adjectives such as starchy.

4.27.2.1.10 Electric taste

Taste thresholds for electric stimulation of the tongue have also been compared in young and elderly subjects. Like thresholds for chemicals, these thresholds tend to be elevated with increasing age (Krarup, B. 1958; Hughes, G. 1969; Nakazato, M. *et al.*, 2002; Terada, T. *et al.*, 2004; Kettaneh, A. *et al.* 2005).

4.27.2.2 Nonuniformity of Taste Loss

It can be seen from the above studies that different stimuli have varying degrees of loss depending upon their chemical structure. This fact is reemphasized by a study of 65 elderly (aged 65–85 years) who were taking no medications other than vitamins. Correlations of taste DTs and RTs for NaCl, quinine HCl (QHCl), and sucrose with one another for unmedicated elderly are given in Table 10. DTs and RTs for a specific tastant were highly correlated with one another: QHCl DT–QHCl RT ($r = 0.69$), NaCl DT–NaCl RT ($r = 0.64$), and sucrose DT–sucrose RT ($r = 0.5$). RTs for NaCl, sucrose, and QHCl were also significantly correlated with one

Table 10 Correlation between thresholds with the same and different taste qualities

	NaCl DT	*NaCl RT*	*Sucrose DT*	*Sucrose RT*	*QHCl DT*	*QHCl RT*
NaCl DT	1.00	0.64, $p < 0.0001$	0.12, $p = 0.1886$	0.19, $p = 0.0304$	0.14, $p = 0.1228$	0.15, $p = 0.0861$
NaCl RT		1.00	0.13, $p = 0.1569$	0.30, $p = 0.0006$	0.17, $p = 0.0616$	0.27, $p = 0.0023$
Sucrose DT			1.00	0.50, $p < 0.0001$	0.08, $p = 0.3920$	0.06, $p = 0.5056$
Sucrose RT				1.00	0.19, $p = 0.0352$	0.26, $p = 0.0029$
QHCl DT					1.00	0.69, $p < 0.0001$
QHCl RT						1.00

another but to a lesser degree than the DTs and RTs for a specific tastant: NaCl RT–sucrose RT ($r = 0.30$), NaCl RT–QHCl RT ($r = 0.27$), and sucrose RT–QHCl RT ($r = 0.26$). All other taste intercorrelations among taste measures in Table 10 were 0.19 or less. Thus, if a person has a loss for the salty taste of NaCl, this does not necessarily mean that the person has a loss for other compounds.

4.27.2.3 Taste Thresholds and Nutritional Value

An interesting trend in threshold concentration levels in Tables 1–9 for both young and elderly is that compounds with high caloric or nutritional value such as sugars, fats, and amino acids tend to have higher DTs than certain noxious bitter compounds that can be detected in minute amounts. One possible explanation for the higher DTs for sugars, amino acids, and fats is that this allows only the high-caloric foods to be perceived in a natural setting rather than foods with low nutritional value. That is, too much taste at low concentrations could inhibit the intake of adequate calories.

4.27.3 Suprathreshold Taste Recognition and Identification

4.27.3.1 Magnitude Estimation

Suprathreshold taste studies using magnitude estimation (which relates the perceived intensity to concentration) show decrements in perceived intensity in the elderly (see Schiffman, S. S., 1997, for review). The slope of the psychophysical function that relates perceived intensity and concentration declines with age for a broad range of stimuli (Schiffman, S. S. and Clark, T. B. 1980; Schiffman, S. S., *et al.*, 1981; Cowart, B. J., 1983; Schiffman, S. S., *et al.*, 1994; Mojet, J. *et al.*, 2003). Cowart B. J. (1983) found that the ratios of slope (young)/slope (elderly) for basic tastes were as follows: sucrose, 1.39; citric acid, 1.30; NaCl, 1.25, and quinine sulfate, 1.73. Schiffman S. S. and Clark T. B. (1980) reported that the slopes of the perceived intensity/concentration curves for 23 amino acids for elderly subjects were always flatter than the slopes for young subjects. The mean ratio of slope (young)/slope (elderly) for all the 23 amino acids was 2.55. However, the ratio of the slopes varied greatly with the amino acids. The ratios for two amino acids with side chain containing acidic groups, L-aspartic acid and L-glutamic acid, were 10.9 and 4.5, respectively, while the ratios for L-lysine and L-proline were only 1.10 and 1.28, respectively.

Schiffman S. S. *et al.* (1981) reported that the mean ratio of slope (young)/slope (elderly) for ten sweeteners (all of those in Table 3 except monellin) was 2.06 with ratios greater than 1.0 for all sweeteners. Although the variability in the slopes for sweeteners was not as great as for amino acids, there was nonuniformity in the flattening of the slopes, which suggests that receptor site compositions for sweeteners can be altered by the aging process. The greatest depression in slope with age was found for thaumatin, rebaudioside, and neohesperidin dihydrochalcone, which are relatively large sweetener molecules with more possible sites for hydrogen bonding with the receptor. Schiffman S. S. *et al.* (1994) also used magnitude estimation to compare slopes for a set of bitter compounds (caffeine, denatonium benzoate, $MgCl_2$, $MgNO_3$, quinine HCl, quinine sulfate, and sucrose octa-acetate) in young and elderly subjects. Both tasters and nontasters of the bitter compound PTC were included as subjects in the study. The mean ratio of slope (young)/slope (elderly) for tasters was 1.76 and the mean ratio of slope (young)/slope (elderly) for nontasters was 1.19. This suggests that suprathreshold loss can be slightly greater for tasters than for nontasters. Mojet J. *et al.* (2003) also reported that the slopes of the psychophysical functions for the sweet, bitter, and umami

tastants in water were flatter in the elderly than in the young. As a group these studies indicate that suprathreshold taste intensity is reduced in elderly persons, and there is evidence for a differential decline based on the chemical structure. The relative contribution of normal aging and other health factors to this decline is not known, however, because medications were not controlled in these studies.

4.27.3.2 Difference Thresholds

Losses also occur in the ability to discriminate between different suprathreshold intensities of the same stimulus. Gilmore M. M. and Murphy C. (1989) found that while young subjects generally needed a 34% difference in concentration to perceive a perceptible difference in the bitterness of caffeine, the elderly required an increment of 74% increase. Schiffman S. S. (1993) reported that while young subjects generally needed only a 6–12% difference in a moderately intense concentration of NaCl to perceive a change, the elderly required an increment of 25% to distinguish a difference in saltiness. Nordin S. *et al.* (2003) also found that difference thresholds for citric acid and NaCl were larger in older individuals.

4.27.3.3 Qualitative Perception in the Elderly

In order to determine if there are any age-related differences in the qualitative taste perception, young and elderly subjects were asked to rate 20 tastants. Each tastant was evaluated on five different adjectives (sweet, sour, salty, bitter, and other) for a total of ten points distributed among the five qualities (Schiffman, S. S., 2000). Subjects were also asked to judge whether each stimulus gave the impression of a single taste (singular) or gave the impression that it existed in the form of two or more component tastes (nonsingular). The mean ratings for sweet, salty, sour, bitter, and other for each tastant in young and elderly subjects along with the percentage of subjects who perceived the tastant as singular are given in Table 11. Several findings emerged from the study. First, neither young nor elderly categorized tastants into four discrete groups; rather the majority of tastes were found to have an other component. That is,

Table 11 Mean quality and singularity ratings of 20 tastants by 12 young and 12 elderly subjects[a]

	Sweet		*Salty*		*Sour*		*Bitter*		*Other*		*Singular (%)*

[a]Subjects rated the taste of each compound on five different scales (sweet, sour, salty, bitter, and other) for a total of 10 points distributed in any way among the five categories. Subjects also judged whether each stimulus was singular (gave the impression of a single taste) or nonsingular (gave the impression that it existed in the form of two or more component tastes).

neither young nor elderly subjects, while wearing nose plugs, limited their ratings of the 20 tastants to sweet, sour, salty, and bitter alone. Second, the magnitude of the total (sum) ratings on other for elderly subjects was greater than for any of the four so-called primary tastes, that is, these stimuli clearly had qualities other than sweet, salty, sour, or bitter. The higher number of off-tastes perceived by the elderly were most likely the result of medications and medical conditions (see Schiffman, S. S., 2007). Third, stimuli that are considered to be primary or basic tastes such as NaCl (salty), urea (bitter), and citric acid (sour) were not found to be any more singular (which one should expect if a taste is basic or unique) than other stimuli for both age groups although the degree of singularity depended on the stimulus.

4.27.3.4 Other Suprathreshold Findings in the Elderly

Murphy C. (1986) found that the elderly tend to find salt and sugar more pleasant at higher concentrations that do younger subjects, which is consistent with the loss of sensitivity. Warwick Z. S. and Schiffman S. S. (1990) found that the fat content in sugar/fat and salt/fat mixtures was unrelated to pleasantness ratings for elderly subjects, which is consistent with the fact that elderly have elevated thresholds for oils. Byrd E. and Gertman S. (1959) found no significant age-related decreases in the ability to identify suprathreshold concentrations of sweet (sucrose), sour (citric acid), salty (NaCl), and bitter (quinine HCl) in water but there was a consistent trend toward diminished positive identification with age. However, the elderly were clearly less able to discriminate between the taste qualities in real food products (Mojet, J. *et al.*, 2004). Schiffman S. (1979) also found that the elderly (while blindfolded) have reduced ability to identify blended foods on the basis of taste (and smell).

4.27.4 Medications Associated with Taste Alterations

Medications can play a major role in taste losses and distortions (Schiffman, S. S. *et al.*, 2002; Schiffman, S. S., 2007) but the majority of taste changes attributed to specific drugs are based on clinical reports rather than on experimental studies. Oral sensory complaints including taste problems are more prevalent in elderly who use medications (Schiffman, S. S., 1997; Schiffman, S. S., and Zervakis, J., 2002; Nagler, R. M. and Hershkovich, O., 2005). Table 12 lists hundreds of medications that have been clinically associated with complaints such as loss of taste, altered taste, and metallic taste. Most major drug classes have been implicated in taste disturbances. However, because quantitative assessments of large populations taking specific medications have not been performed, it is not yet known whether clinically reported taste complaints (e.g., case reports) are indeed gustatory or olfactory in nature, or if they are actually caused by medications or the medical conditions they are designed to treat. Furthermore, according to the Physicians' Desk Reference (2000–2005), adverse taste complaints from medications afflict only a minority of patients taking a drug but the actual prevalence of medication-induced losses awaits determination by experimental testing procedures.

Table 12 (Continued)

Methamphetamine HCl
Phendimetrazine tartrate
Phentermine resin and phentermine HCl

Vasodilators
Bamifylline hydrochloride
Diltiazem
Dipyridamole
Isosorbide mononitrate
Nitroglycerin patch
Oxyfedrine

Others (indication)
Allopurinol (reduces serum and urinary uric acid)
Antihemophilic factor (recombinant) (clotting factor – hemophilia)
Antithrombin III (human) (antithrombin III deficiency)
Calcitonin (Paget's disease, hypercalcemia, osteoporosis)
Cyclosporine (prevent rejection of liver, heart, and kidney transplants)
Etidronate (hypercalcemia, antipsoriatic)
Etretinate (antipsoriatic)
Germine monoacetate (Eaton–Lambert syndrome)
Granisetron HCl (antiemetic/antinauseant)
Histamine phosphate (control for allergic skin testing)
Iohexol (diagnostic imaging product)
Iron sorbitex (hematinic)
Leuprolide acetate (inhibits gonadotropin secretion/ prostatic cancer)
Levamisole HCl (immunomodulator – restores depressed immune function)
Mesna (detoxifying agent)
Methazolamide (carbonic anhydrase inhibitor)
Methylergonovine maleate (prevents postpartum hemorrhage)
Midodrine (hypotension)
Nicotine (smoking cessation)
Nicotine polacrilex (smoking cessation)
Oxycodone HCl (pain)
Pentoxifylline (blood viscosity modulator)
Potassium iodide (expectorant)
Sermorelin acetate (diagnostic)
Succimer (lead poisoning)
Terbinafine
Ursodiol (gall stone dissolution)
Vitamin D/calcitriol (hypocalcemia)
Vitamin K1/phytonadione (coagulation disorders)

See Schiffman S. S. and Zervakis J. (2002) for more details.

Currently, little is known about the sites of action or cascade of cellular events by which medications induce taste complaints. However, medications can impact taste perception at several levels of the nervous system including the peripheral receptors, chemosensory neural pathways, and/or the brainstem and brain. Medications can induce a taste at receptor sites that are localized on either the apical or the basolateral membranes of taste cells. The plasma concentrations of some drugs (e.g., saquinavir) are greater than the taste thresholds and thus can activate receptors on the blood side of taste cells (Schiffman, S. S. *et al*., 1999). For most drugs, however, the salivary or plasma concentrations of drugs tend to be lower than the taste threshold values (see Schiffman, S. S. *et al*., 2002). Yet, drugs or their metabolites can accumulate in taste buds over time to reach concentrations that are greater than taste DTs. Drugs can also alter taste transduction mechanisms or can permeate the blood–brain barrier to interfere with taste signaling at the neural levels.

4.27.5 Medical Conditions Associated with Taste Complaints

A vast range of medical conditions has been reported to affect the sense of taste (Table 13), and clinical studies of wasting patients indicate that taste losses are especially severe (Schiffman, S. S., 1983; Schiffman, S. S., and Wedral, E., 1996). However, in most of these studies, patients who were evaluated for taste perception were also being treated with medications for their medical condition, so it is impossible to determine the relative contribution of disease states and medications to taste losses. Cancer is an example of a chronic medical condition in which patients are especially vulnerable to taste disorders (Schiffman, S. S. and Graham, B. G., 2000). Taste changes occur both in untreated cancer patients (Brewin, T. B., 1980; Ovesen, L. *et al*., 1991) and those treated with chemotherapy (Nielsen, S. S. *et al*., 1980; Fetting, J. *et al*., 1985; Lindley, C. *et al*., 1996) and radiation (Conger, A. D., 1973).

Cancer disproportionately impacts the elderly (Cohen, H. J., 1998) with 60% of all malignant tumors diagnosed in persons aged 65 years and above. Furthermore, 69% of all cancer deaths occur in this age group. Table 14 gives an overview of the taste changes that have been measured in cancer patients using various psychophysical testing techniques. The data suggest that cancer and its treatment impair the ability to detect the presence of basic tastes, reduce the perceived intensity of suprathreshold concentrations of tastants, and interfere with the ability to discriminate and identify tastes and smells. Threshold losses have also been detected using electrogustometry (Berteretche, M. V. *et al*., 2004). Table 15 gives an overview of the food aversions, complaints, and altered preferences reported by cancer patients.

Table 13 Medical conditions associated clinically and experimentally with taste loss

Nervous system disorders
Alzheimer's disease
Bell's palsy
Damage to chorda tympani
Guillain–Barre syndrome
Familial dysautonomia
Head trauma
Multiple sclerosis
Raeder's paratrigeminal syndrome
Tumors and lesions
Nutritional disorders
Cancer
Chronic renal failure
Liver disease including cirrhosis
Niacin (vitamin B_3) deficiency
Thermal burn
Zinc deficiency
Endocrine disorders
Adrenal cortical insufficiency
Congenital adrenal hyperplasia
Cretinism
Cushing's syndrome
Panhypopituitarism
Hypothyroidism
Diabetes mellitus
Gonadal dysgenesis (Turner's syndrome)
Pseudohypoparathyroidism
Local disorders
Facial hypoplasia
Glossitis and other oral disorders
Leprosy
Oral Crohn's disease
Radiation therapy
Sjögren's syndrome
Other
Amyloidosis and sarcoidosis
Cystic fibrosis
High altitude
Hypertension
Influenza-like infections
Laryngectomy
Major depressive disorder

See Schiffman S. S. and Zervakis J. (2002) for more details.

These data suggest that at least half of the cancer patients may have impaired taste functioning at some point during the course of their disease and treatment (e.g., DeWys, W. D. and Walters, K., 1975). The duration of losses can last from several weeks to 6 months or more (Conger, A. D., 1973; Mossman, K. *et al.*, 1982; Ophir, D. *et al.*, 1988; Maes, A. *et al.*, 2002).

The causes of altered taste perception in cancer are not well understood but metabolic changes induced by the presence of a neoplasm as well as damage to the sensory receptors by radio- and chemotherapies are likely involved. Radiation therapy and chemotherapy not only affect the turnover of taste and smell receptors but can also alter the anatomical integrity of the taste bud. Oral complications of cancer such as infections (fungal, viral, bacterial), ulcers, drug-induced stomatitis, and dry mouth may also play a role. In a recent study, tasting of the bitterness of 6-*n*-propylthiouracil (PROP) bitterness was also associated with the development of colonic neoplasms (Basson, M. D., *et al.*, 2005). The ability to taste the bitterness of PROP is genetically determined. The presumed reason for this association was that persons who perceive the bitter taste PROP would be more likely to avoid foods such as vegetables that are high in antioxidants.

4.27.6 Cause of Taste Losses in the Absence of Drugs and Disease

The cause of taste changes in the elderly in the absence of medications and disease is not fully understood. Early studies with large sample sizes suggested that losses in the number of papillae and/or taste buds occurred in the elderly (Arey, L. B. *et al.*, 1935; Mochizuki, Y., 1937; 1939; Moses, S. W. *et al.*, 1967). However, later studies in a smaller number of older individuals suggested that such losses with age are minimal (Arvidson, A., 1979; Miller, I. J., Jr., 1986; Bradley, R. M., 1988; Miller, I. J., Jr., 1988). These later studies are difficult to reconcile with earlier studies and with more recent psychophysical studies that show striking localized deficits (i.e., regional losses) in taste perception over different areas of the tongue in older individuals (Bartoshuk, L. M. *et al.*, 1987; Matsuda, T. and Doty, R. L., 1995). Furthermore, studies of the lingual surface have found entirely flat areas on the surface of the tongue without papillae in old age (Kobayashi, K. *et al.*, 2001).

Reduced renewal of taste cells may account for some age-related losses. While taste cells normally replicate every 10–10.5 days (Beidler, L. M. and Smallman, R. L., 1965), delayed cell renewal and highly vacuolated cytoplasm have been reported to occur in taste buds of aged mice (Fukunaga, A., 2005). Decreased levels of estrogen and testosterone in the elderly may play a role in reduced cell renewal in taste buds since animal models indicate that estrogen and testosterone increase mitotic activity (Eartly, H. *et al.*, 1951; Zhang, Z. *et al.*, 1998). Endocrine factors

Table 14 Alterations of taste performance in cancer patients

Taste loss	*Type of cancer*	*Effect of therapy*	*Reference*
Elevated detection and recognition thresholds for NaCl (salt), sucrose (sweet), HCl (sour), and urea (bitter) prior to radiotherapy; salty, sweet, and bitter further impaired by radiotherapy	Various malignant neoplasms	Radiotherapy further impaired taste loss	Bolze M. S. *et al.* (1982)
Elevated recognition thresholds for sucrose (sweet), HCl (sour), quinine HCl (bitter) during radiotherapy; recovery by 120 days	Oropharyngeal cancers	Radiotherapy	Conger A. D. (1973)
Elevated detection and recognition thresholds, especially for bitter and salt thresholds during radiotherapy	Head and neck	Radiotherapy	Mossman K. L. and Henkin R. I. (1978)
Elevated NaCl (salty) recognition thresholds	Breast and colon	Prior to treatment	Carson J. A. and Gormican A. (1977)
Elevated recognition threshold for hydrochloric acid (sour); individual differences in bitter and sweet threshold changes	Lung	Prior to therapy	Williams L. R. and Cohen M. H. (1978)
Elevated taste recognition thresholds for NaCl, sucrose, quinine sulfate, picric acid; thresholds returned to normal 6 weeks post-treatment	Oropharyngeal	During and after radiotherapy	Kalmus H. and Farnsworth D. (1959)
Thresholds for NaCl (salt), tartaric acid (sour), sucrose (sweet), and quinine (bitter) elevated by radiation and chemotherapy; recovery was not complete by 1 year	Oral squamous cell carcinoma	Radiation and chemotherapy	Tomita Y. and Osaki T. (1990)
Elevated glucose recognition threshold	Various malignant neoplasms	During chemotherapy	Bruera E. *et al.* (1984)
Significant increase in electrical taste detection threshold; no change in smell threshold	Lung, ovary, and breast	Increase in untreated patients; thresholds decreased only in patients who responded to chemotherapy (after 2 to 3 months)	Ovesen L. *et al.* (1991)
Significant decrease in recognition threshold for urea (bitter)	Gastrointestinal		Hall J. C. *et al.* (1980)
Loss of ability to discriminate between different concentrations of salt, sweet, sour, and bitter	Melanoma	During nine courses of chemotherapy	Mulder N. H. *et al.* (1983)
Significant reduction in smell identification in patients with estrogen receptor; positive breast cancer	Breast cancer	Mixed sample (treated and untreated)	Lehrer S. *et al.* (1985)

including castration and thyroidectomy have long been known to depress cell proliferation in other tissues such as small-bowel epithelium (Hopper, A. F. *et al.*, 1972; Williamson, R. C., 1978). There may be some shrinkage of taste projection areas in the brainstem because images of the cross section of the upper part of the medulla oblongata suggest slight reductions in size with age and tooth loss in some individuals (Yamamoto, T. *et al.*, 2005). Decreased performance on psychophysical taste tests in the elderly can also be related to structural changes in the hippocampus and amygdala (Scheibel, M. E. and Scheibel, A. B., 1975; Tomlinson, B. E. and Henderson, G., 1976). Damage to the amygdala and the hippocampus has been shown to interfere with registering and valuing behavior (Pribram, K. H. 1971). Environmental pollutants can also impact taste receptors and/or projections to the central nervous system (Schiffman, S. S. and Nagle, H. T., 1992). Hyposalivation and low perceived salivary flow have also been reported to lower satisfaction with tasting foods (Ikebe, K. *et al.*, 2002).

Table 15 Taste complaints and altered food preferences in cancer patients

Sensory loss	*Type of cancer*	*Effect of therapy*	*Reference*
Food aversions and cravings	Various malignant neoplasms	Radiotherapy	Brewin T. B. (1982)
Reduced palatability of high-protein foods, cereals, and sweets in patients with taste aversions	Various	Treated and untreated	Vickers Z. M. *et al.* (1981)
All food tasted nauseating, greasy or rancid; wine tasted metallic; water tasted salty	Oropharyngeal	Developed during first two weeks of radiotherapy	Kalmus H. and Farnsworth D. (1959)
Patients developed aversions to sweets, meats, caffeinated beverages, high fat and greasy foods during therapy	Breast and lung	Prior to and during chemotherapy	Mattes R. D. *et al.* (1987)
Symptom of reduced appetite correlates with elevated recognition threshold for sucrose (sweet); meat aversion correlates with lowered thresholds for urea (bitter)	Various		DeWys W. D. and Walters K. (1975)
Highly varied hedonic responses to beverages containing five suprathreshold concentrations of citric acid (in lemonade), NaCl (in unsalted tomato juice), urea (in tonic water), and sucrose (in cherry drink); anorectics preferred lower sweetness levels than nonanorectics; yet sweet foods constituted a greater percentage of their daily caloric intake	Upper gastrointestinal and lung	Patients on chemotherapy had less distinct preference for any of the five concentrations of sucrose, particularly high levels	Trant A. S. *et al.* (1982)
Percentage of patients reporting taste problems increased from 18% prior to radiation to over 80% during the 5th week of radiation; foods with abnormal taste included high-protein foods (meat, eggs, dairy), fruits, vegetables, sweet, breads, cereal, coffee, and tea	Head and neck cancer	During radiotherapy	Chencharick J. D. and Mossman K. L. (1983)
Complaints of metallic, bitter, or decreased taste; distorted sweet taste	Breast and lung	Chemotherapy – cisplatin	Rhodes V. A. *et al.* (1994)

The mechanism for some taste losses may also involve neurodegeneration that can accompany cytokine-mediated inflammatory processes (see Viviani, B. *et al.*, 2004, for description). Inflammatory processes involving cytokines and inflammation mediators with subsequent cell death have been implicated in age-related losses in olfaction (Ge, Y. *et al.*, 2002; Conley, D. B. *et al.*, 2003; Kern, R. C. *et al.*, 2004; Raviv, J. R. and Kern, R. C., 2004). Similarly, taste alterations subsequent to infection as well as losses in normal aging may also be caused by the neurotoxic effects of cytokines and mediators. It is noteworthy that impairments in taste perception are associated with the presence of *Candida albicans* in the oral cavity (Sakashita, S. *et al.*, 2004). A general decline in immune functioning, including cytokine dysregulation, is a hallmark of aging (Wilson, C. J. *et al.*, 2002). Thus, inflammatory processes that induce neural damage and apoptosis in the taste system may account for reduced sensitivity from normal aging as well as from infections. Environmental pollutants may play a role in the inflammatory processes (see Schiffman, S. S. and Nagle, H. T., 1992).

4.27.7 Final Comment

Losses in taste perception occur in the elderly with elevated DTs and RTs as well as decrements in perceived suprathreshold intensity. While loss in taste sensitivity occurs during normal aging in the absence of disease or medications, losses can be significantly exacerbated by medical conditions and drugs. Dysgeusia increases in persons taking

medications (e.g., cardiac medications), but the relative contribution of medications and medical conditions to these taste distortions is not fully understood.

4.28.1 Outline of the Olfactory Signal Transduction

During the past decades, a huge amount of knowledge has been accumulated in the research filed regarding the molecular mechanisms mediating olfactory energy conversion. The outline of this signal transduction is summarized as follows (see Figures 2(a) and 6). In the genomic DNA, the olfactory receptor cells (ORCs) prepare multiple types of genes encoding seven-transmembrane-domain receptors. Individual receptor cells select only one type of receptor protein gene for the functional expression on their ciliary surface. The receptor proteins are coupled to the olfaction-specific G protein (termed G_{olf}) that activates type-III adenylyl cyclase (AC). This enzyme converts cytoplasmic ATP to cyclic AMP (cAMP). These sequential chemical reactions finally lead to the openings of ion channels that underlie cell excitation (transduction channel). Although the natural ligands for olfaction have large diversity exceeding 100 000 varieties, the signal thus converges into only one type of second messenger, cAMP, through the enzymatic cascade equipped in the sensory cilia. Another parallel pathway utilizing phospholipase C (PLC) – $InsP_3$ – may coexist for the chemical sensation for particular species of animals and/or odorants.

4.28.2 Receptor Potential as an Initial Membrane Excitation

As in the general neurons, excitation of the ORCs is the change in the electrical potential across the plasma membrane. The resting membrane potential is set at −50 to −70 mV. Odorant stimulation induces depolarization (change in the membrane potential to the positive direction; Figure 1).

The key molecular element that converts the chemical energy into the biological signal is the transduction channel located in the ciliary membrane. Openings of transduction channels cause a change in the membrane potential depending on the input resistance of the ORC membrane. Usually, the input resistance of the ORC is >5 GΩ, and therefore, only 1 pA of current can induce >5 mV of change in the membrane potential. This initial depolarization is called the receptor potential. The time course of the receptor potential is roughly the same as the time course of opening and closing of the transduction channel. This potential change is characterized by its graded property; information about the strength of the stimulants is represented as a magnitude of the depolarization (Figure 1). Since this potential is slow and graded, it cannot conduct to the brain along the thin and long axon; its amplitude is exponentially reduced with the longitudinal

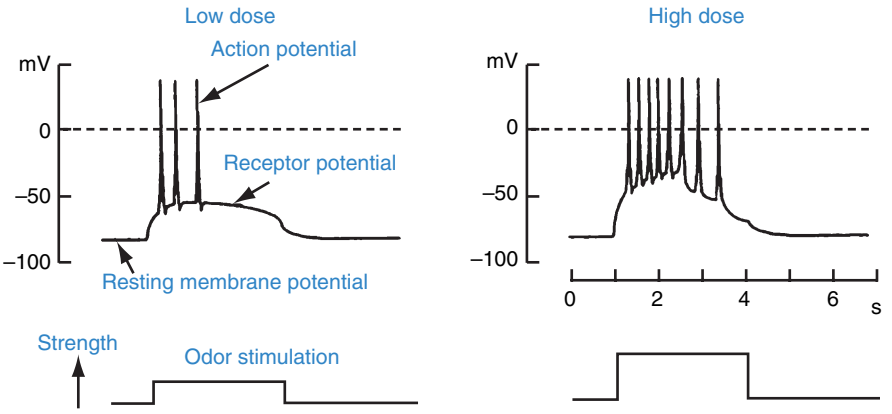

Figure 1 Membrane excitation of the single ORC to low and high doses of odorant stimuli.

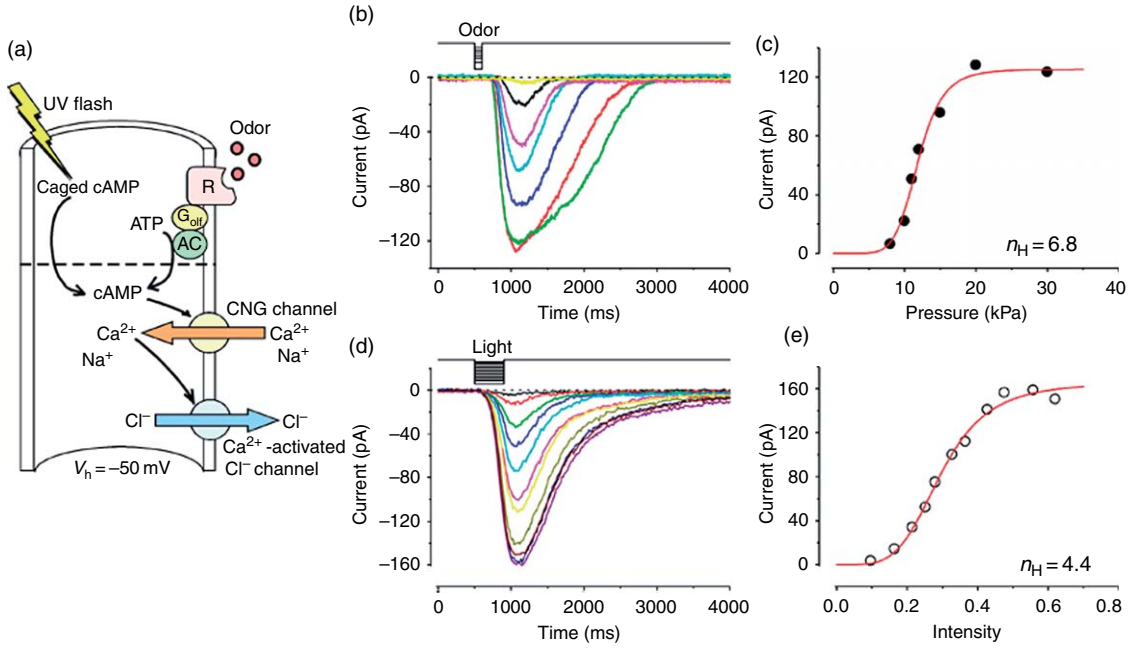

Figure 2 Dose–response relation of single ORCs. (a) Olfactory cilia were stimulated both by odorant and cytoplasmic cAMP emitted by the photolysis of caged cAMP. (b) Odorant-induced response. (c) Dose–response relation. (d) cAMP-induced response. Different cell from (b). (e) Intensity–response relation. Adapted from Takeuchi, H. and Kurahashi, T. 2005. Mechanism of signal amplification in the olfactory sensory cilia. J. Neurosci. 25(48), 11084–11091.

distance from the generation site (cilia). In order to transmit the odorant information to the brain, ORCs induce self-regenerating action potentials (spikes) that do not show signal decay during its conduction. In the action potentials, firing frequencies represent the information about the strength of the stimulants.

The transduction current is unique, in that the magnitude of the excitation shows a very high cooperativity; a small change in the odorant dose is reflected to a big change in the response amplitude. When the inward current responses recorded under the whole-cell voltage-clamp condition are plotted versus stimulus strength, the relation is fitted by the Hill equation (eqn [1]) with very high Hill coefficient (n_H),

$$I = I_{max} \frac{C^{n_H}}{C^{n_H} + K_{1/2}^{n_H}} \quad [1]$$

where I is the current, C is the dose of the ligand, and $K_{1/2}$ is the half-maximum dose. Hill coefficient is an index to express cooperativity and is about 5–6 (Figure 2). If there is no cooperativity, this number becomes 1. Since the same n_H value can be obtained when the cytoplasmic cAMP concentration ($[cAMP]_i$) is increased by the photolysis of caged

cAMP, the high cooperativity is concluded to be achieved after the cAMP production (see below for the detailed mechanisms).

4.28.3 Differences of Single Olfactory Receptor Cells in Functional Ligand Affinities

As described in earlier chapters, genomic DNA contains a large family of genes encoding the odorant receptors, and individual ORCs choose only one type of gene for functional expression. Therefore, investigating the spectrum of single ORCs is equivalent to the survey of the functional spectrum of single odorant receptor in native cells. Since the number of ligand is over 100 000 and since the number of the odorant receptor is 100–1000, it is obvious that the binding of odorants to the odorant receptor is one to many.

When single ORCs were stimulated by two different species of odorants, ORCs show a variety of responsiveness, including cells responding to either types of odorants, cells responding to both, and cells responding to neither (Figure 3). The presence of cells responding to different types of odorants indicates that the single odorant receptor can bind to many different odorants. One may think that the ligand–receptor interaction is an independent event (i.e., random bindings of ligands into the receptors). It seems likely, however, that in the ORCs, the odorant receptors have preferential recognition for certain spectrum of odorants. When the responsiveness to both cineole and lilial stimuli are examined in single receptor cells, there is a positive dependence in the conditional probabilities (therefore the positive correlations, Figure 3(c)); cells responding to cineole are observed in cells responding to lilial more frequently than in cells insensitive to lilial, vice versa cells responding to lilial are observed in cells responding to cineole more frequently than in cells insensitive to cineole (Figure 3(d)). There may be some correlation between the preference of the odorant receptor and the quality of the smell. At this point, unfortunately, there is no systematic study in the receptor preference of ligands and needs to be clarified in future.

4.28.4 Can Olfactory Receptor Cells Detect a Single Odorant Molecule?

In vision, the rod photoreceptor cell can detect a signal from the quantum unit of light, a single photon. Following this knowledge, scientists have been looking for the unitary events in the olfactory response; namely, a response induced by a single odorant molecule. In 1995, Menini and co-workers reported that the response of single ORCs to a low concentration of odorant (*c.* 1 μM, detecting-threshold dose) was very noisy. The noise component was observed as bump-like events, and they suggested that these bump responses may express unitary events caused by the hitting of single odorant molecules to the single olfactory receptor proteins. The amplitude of the events was approximately 1 pA. Immediately after their observations, however, Lowe and Gold showed that application of cAMP into the cytoplasm of the ORCs causes responses with very similar profile as odorant responses that have bump-like current

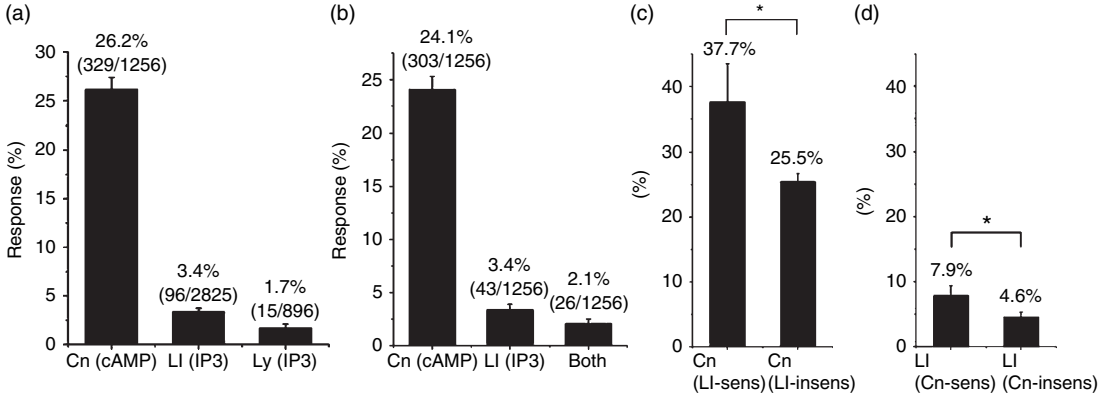

Figure 3 Responsiveness of single ORCs to odorants. (a) Responsiveness to cineole (Cn), lilial (LI), and lyral (Ly). (b) Responsiveness of single ORCs when cells were stimulated by both Cn and LI. (c and d) Conditional probabilities derived from the experiment of (b) Adapted from Takeuchi, H., Imanaka, Y., Hirono, J., and Kurahashi, T. 2003. Cross-adaptation between olfactory responses induced by two subgroups of odorant molecules. J. Gen. Physiol. 122, 255–264.

fluctuations. Since there is no odorants in the experiments that employed the cAMP introduction, bump-like current responses are not attributable to the odorant bindings to the receptors. Their interpretation for the bump response is that the olfactory signal transduction is intrinsically noisy and that the basal noise is clipped off by a strong nonlinear amplification established by the sequential openings of two types of ionic channels: cyclic nucleotide-gated (CNG) and Cl^- channels (see Section 4.28.9).

Just very recently, Bhandawat and co-workers showed that unitary events for olfactory transduction were observed only when the Ca ions were removed from the surrounding media. In this specific condition, the amplitude of the unitary events was 0.9 pA. At the physiological condition containing Ca^{2+}, however, unitary events became undetectable and could be estimated only with a noise analysis by variance/mean–mean relationship and were estimated to be 0.01 pA. This value is very small; even smaller than the basal fluctuations by the intrinsic noise. It thus seems unlikely that the unitary events for the single odorant detection are observed as an olfactory response. One may feel this feature in the ORC quite puzzling, in that rod photoreceptors can detect single photon. However, even among the photoreceptor cell, cone-type photoreceptor cells are not able to detect single photon. In this sense, it is rather appropriate to consider that the rod photoreceptor cell is specifically adapted to have a unique and strong amplification system. As for the signal amplification in the ORC, a recent work by Takeuchi and Kurahashi has directly shown that the enzymatic processes of olfactory sensory cilia have low amplification (see Section 4.28.9).

4.28.5 Enzyme – Second Messenger: cyclic AMP and $InsP_3$

For a long period of time, it has been believed that two independent pathways utilizing either AC-cAMP system or the PLC-InsP3 system mediate the olfactory signal transduction. In other words, odorant species are divided into two subgroups: one is called the cAMP odorant and another $InsP_3$ odorant (for history and evidence, see Schild, D. and Restrepo, D., 1998). There have been several approaches that have tried to identify the second messenger mediating olfactory transduction. Gold and his collaborators used gene-targeting methods to find out if electro-olfactogram (EOG) responses are affected in mice that lacks molecular elements constituting the cAMP pathway (CNG channels; G_{olf}; AC type III). EOG responses to $InsP_3$ odorants were abolished or reduced in animals that lacked any of those elemental proteins. In addition, Zufall's group showed that the inhibitor of AC reduced the response induced by $InsP_3$ odorants. In a recent work by Takeuchi and co-workers, the effects of cytoplasmic cNMPs in sensory cilia were directly examined in cells that retained their response abilities to odorants (including $InsP_3$ odorants). They showed that responses induced by both cAMP and $InsP_3$ odorants resemble each other and show almost perfect symmetrical cross-adaptation. The degree of cross-adaptation between the cAMP odorant and the $InsP_3$ odorant matched perfectly, which cannot be explained simply by coincidences in parallel systems. Furthermore, they showed that the response induced by the cytoplasmic cAMP is changed depending on the dose of $InsP_3$ odorants (Figure 4). The additive

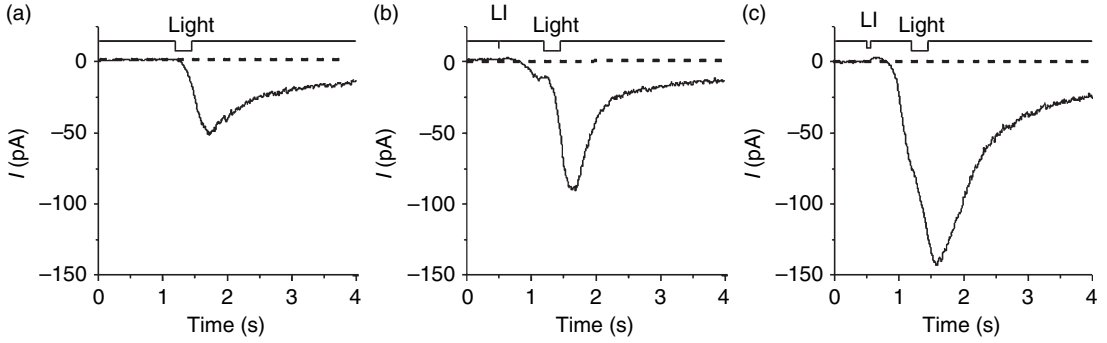

Figure 4 Summation of cAMP-induced current on the lilial (LI)-induced current in the single ORC. Cytoplasmic cAMP was jumped by a flash photolysis of caged cAMP. Lilial stimuli were applied from the puffer pipette to the cilia. Note that the amplitude of cAMP response (light) is affected by the presence of the lilial. Takeuchi, H. and Kurahashi, T. 2003. Identification of second messenger mediating signal transduction in the olfactory receptor cell. J. Gen. Physiol. 122(5), 557–567.

effects could be explained by assuming that $InsP_3$ odorants do increase the cytoplasmic cAMP. All together, it is highly likely that the main stream of olfactory signal transduction is uniformly mediated by cAMP for a wide variety of odorants through a universal second messenger.

Just very recently, however, Restrepo's group showed that mice lacking their CNG channels could still have abilities of responding to particular types of odorants. This result indicates that there is a pathway that is independent from the cAMP-mediated pathway. However, EOG responses in mutant mice were all reduced in comparison to those observed in the wild type. Nonlinear summation observed in the $InsP_3$ odorant response (see Figure 4) does indicate the increase of cAMP, but does not completely rule out the possibilities for the some fractions responses to be evoked in the $InsP_3$-mediated pathway. Coupled with the fact that ORCs in some particular animals (e.g., lobster) use $InsP_3$ as a second messenger, certain fraction of the responses may be mediated by the $InsP_3$-dependent pathway.

4.28.6 Cyclic Nucleotide-Gated Channel

The discovery of cationic channel that is directly gated by cytoplasmic cyclic nucleotide was first made on a work applied to the rod photoreceptor cell. This finding actually ended the long-standing question of what kind of substance (second messenger) transmits the information from the disk membrane (where photopigments are located) to the plasma membrane (where ionic channels mediating cell excitation are present). This historical finding provided a big impact not only on the research on the photoreceptor cell, but also for the research on other sensory and neuronal signal transduction system. Nakamura T. and Gold G.H. (1987) applied the inside-out patch clamp method onto the ciliary membrane of the toad ORC and confirmed electrophysiologically the presence of homologous channel in the ORC. Following the electrophysiological evidence, the gene that encodes the CNG channel was identified. The amino acid sequences of the cloned CNG channels have high identity between rod and ORCs. Both express six membrane-spanning domains and one pore region (Figure 5). The ionic channel is cation-selective, and this is well consistent with the fact that the odorant-activated channels are cation-selective when measured under the Ca^{2+}-free condition (therefore no involvements of Cl^- component).

It is speculated now that the native olfactory channel consists of tetramer using three alpha subunits (CNGA2 and CNGA4) and one beta subunit CNGB1b (stoichiometry 2:1:1 CNGA2:CNGA4:CNGB1b). Among them, CNGA4 subunit seems to be essential to establish Ca^{2+}-calmodulin (Ca-CAM) effect that regulates the olfactory adaptation (see Section 4.28.10).

In the amphibian, CNG channels express a strong localization to the ciliary membrane where olfactory transduction takes place. The density of the channels are as high as 1000 μm^{-2}. In the rodents, however, the distribution of the CNG channels seems to be relatively spread. At this point, there is no physiological explanation why CNG channels are strongly polarized in the amphibian and why they are spread over the cell in the rodent.

Single events for the CNG current can be directly observed when the divalent cations were

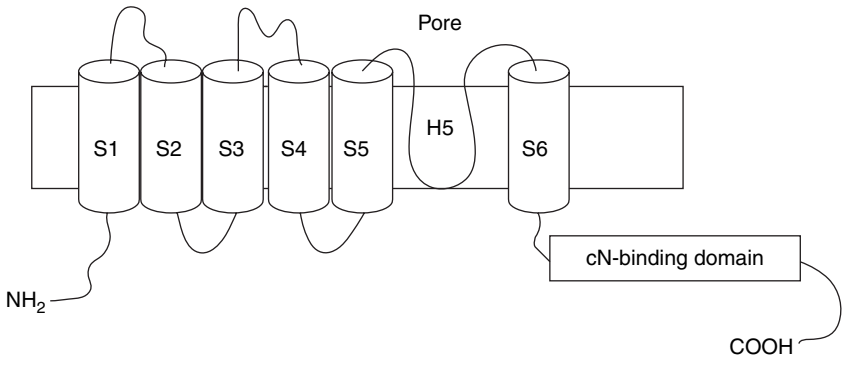

Figure 5 Structure of the subunit of the CNG channel. Both N- and C-terminals are located in the cytoplasmic side. There are six transmembrane domains (S1–S6) and one loop region (H5).

removed from the media. The size of unitary current is about 1 pA when the membrane potential is held at +50 mV. Open–close transition is about the order of 100 ms. In the presence of physiological Ca^{2+} and Mg^{2+}, however, such unitary conductance cannot be observed, because of a flickering-block of channels by divalent cations. This makes the channel event extremely small. Furthermore, the channel density is extremely high. These features allow the summed transduction current to express very high S/N ratio.

4.28.7 Ca^{2+}-Activated Cl^- Channel

Kleene S. and Gesteland R. C. (1991) first reported that olfactory sensory cilia contained Cl^- channels that were sensitive to cytoplasmic Ca^{2+}. Since CNG channels have a very high permeability to Ca^{2+} ($P_{Ca}/P_{Na} = 6.5$), opening of the CNG channel allows Ca^{2+} to enter into the ciliary cytoplasm during the odorant response, which leads to the activation of Ca^{2+}-activated Cl^- channels located in the cilia. Initially, the real function of the Cl^- channel was not identified, and a likely possibility assumed at that point was that Cl^- channel may be responsible for the hyperpolarization of the cell; generally, in neurons, Cl^- channels are functional for generating inhibitory responses. Kurahashi T. and Yau K. W. (1993) demonstrated, however, that in the newt ORCs, the transduction inward current actually consists of two ionic components, cationic and anionic currents. Surprisingly, the Cl^- current was inward, which causes a membrane depolarization. In 1995, Ache's group showed that cytoplasmic Cl^- concentration in the ORC was high enough to induce depolarizing response. Recent works revealed that Cl ions are up-taken into the cell with an Na^+–K^+–$2Cl^-$ co-transporter called NKCC1.

As for the physiological roles of this unusual Cl^- channel, there are two possible molecular functions proposed for the ORC. First, asymmetrical ion flow achieved by the both cations and anions may serve a stability of the inward current under unstable ionic conditions which seems to be caused quite frequently in the olfactory organ that is directly exposed to the external environment. Second, addition of the sequential ion channel causes a boosting of the total current, providing a signal amplification. Especially with both CNG and Cl^- currents having high cooperativities (Hill coefficient of about 2 for each), the final current expresses extremely high nonlinear amplification (cooperativity of 5–6; see Figure 1).

Ca^{2+}-activated Cl^- channel has a unitary conductance of 0.8 pS and the density 70 channels μm^{-2}, when measured with the noise analysis method (by Kleene). Similar to the CNG channels, this channel has small unitary event and the high density. Again these features establish a signal transduction with high S/N ratio. At this point, unfortunately, the molecular structure of this Cl^- channel is not yet identified.

4.28.8 Ca^{2+}-Activated K^+ Channel (Possibility for the Inhibitory Response)

Potassium channel that is directly gated by cytoplasmic Ca^{2+} is commonly distributed to the neuronal system including the ORC. Bacigalupo's group has shown that the olfactory sensory cilia contain this type of channel with inside-out preparation and the immuno-cyto-chemistry. With the same mechanism as the Ca^{2+}-activated Cl^- channel, it is very likely that this K^+ channel is open when the CNG channel allows Ca^{2+} to enter the ciliary cytoplasm.

However, the physiological role of this K^+ channel is still under speculation. One of the most intriguing possibilities is that the opening of K^+ channel may induce cell hyperpolarization and therefore cause inhibitory responses in the ORC activities. Although the actual equilibrium potential for K^+ at the sensory cilia is not identified in the ORC, common sense of the neuronal system is that K^+ channel is inhibitory. Since very early stage of electrophysiological works on ORCs, it has been reported that certain types of odorants and ORCs express inhibitory responses. These cells may express a large number of K^+ channels on their ciliary plasma membrane.

4.28.9 Signal Amplification: Comparison with the Phototransduction

For a long period of time, researches on olfactory transduction system have been limited on rather qualitative descriptions because of experimental difficulties accompanying the use of diverse ligands, multiple receptors, and the fine structure of the sensory cilia. By overcoming those experimental

difficulties, a recent work by Takeuchi and Kurahashi was conducted to understand the mechanism of signal amplification in the olfactory transduction system. cAMP dynamics was inversely estimated from the activities of CNG channels. As a result, cAMP-production rate was in an order of 2×10^4 s^{-1} per cilium at the maximum odorant stimulus. The cAMP molecules must be produced from many odorant receptors on the ciliary surface (immunostaining against the receptor protein generally shows their presences to be homogeneous, spanning the entire cilia). It is therefore suggested that the odorant receptor triggers very small activities of enzymatic reaction.

It has been pointed out that the olfactory transduction system is very homologous as the phototransduction system, in that both systems are mediated by receptor – G protein – effecter enzyme and the CNG channel. In the rod photoreceptor cell, light-activated protein reactions have been fairly well described. Activation of single rhodopsin by a single photon triggers 10^2–10^3 molecular changes in transducin–phosphodiesterase (PDE) cascade, which leads to the breakdown of 10^4–10^5 cGMP molecules in a second (Figure 6). This number is much bigger than that observed in the ORC, as is obvious in a comparison between extreme opposite situations, maximum versus unitary rates.

As described before, Bhandawat *et al.* showed that the olfactory unitary event, presumably evoked by a single odorant molecule, could be very small. They considered that such small unitary event was attributable to that the lifetime of individual odorant receptor molecules was very short (i.e., 1 ms). As comparison, in rods, a single photon switches the status of single rhodopsin molecule into an active form that lasts for >1 s. During its long lifetime, many transducin–PDE molecules are activated, which leads to the generation of the single photon response. Since the excitation of the single rhodopsin by a single photon is by chance and very instantaneous, rods may have to acquire a high amplification at the receptor–enzyme level. In case of chemical sensations, however, stimulants can be staying around until they are removed.

Nevertheless, it may be still puzzling that the olfactory enzymes use very low signal amplification. In olfaction, however, activation of G-protein-coupled receptor (GPCR) produces cAMP, instead of the breakdown of cGMP in the rod. Therefore, the low amplification in olfactory enzymes would be an efficient way to avoid loss of ATP. Apparently, signal transduction with a small number of molecules is achieved by the fine ciliary structure that has high surface–volume ratio in which even a small change in the absolute number of molecules is reflected as a big change in the concentration. In addition, the ORC has a unique and strong nonlinear amplification detecting a slight change in the odorant dose, which is regulated by Ca^{2+} that flows through the CNG channel; cytoplasmic increase of Ca^{2+} in turn activates excitatory Cl^- current to boost the net

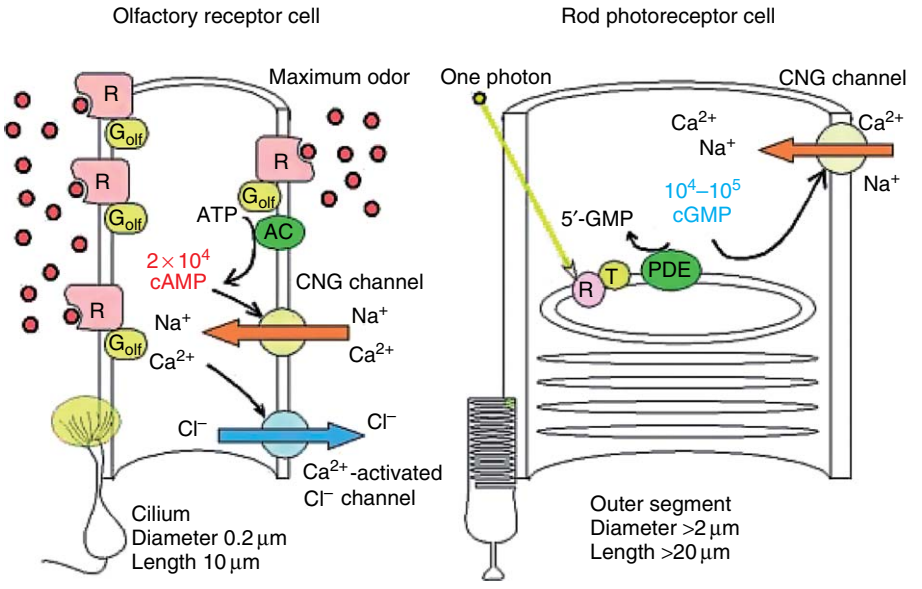

Figure 6 Mechanisms of olfactory transduction and phototransduction.

transduction current. Thus, the sequential openings of two ion channels establish a high nonlinear amplification in olfaction, utilizing Ca^{2+} as a third messenger that is not present in the phototransduction system.

4.28.10 Adaptation

It has been known that the olfactory sensation becomes gradually smaller during the long exposure to the odorant environment (Figure 7(a)). Also, when the odorant pulses are delivered twice, the secondary response becomes smaller than the initial response. The reduced response becomes recovered as the inter-interval is prolonged (Figure 8).

These phenomena are generally called as fatigue, desensitization, or adaptation. One may use these words to the same concept when the response amplitude is gradually reduced as time processed. However, the fundamental concepts are thought to be different.

Among them, the word adaptation is used especially when the dose–response relation is shifted to

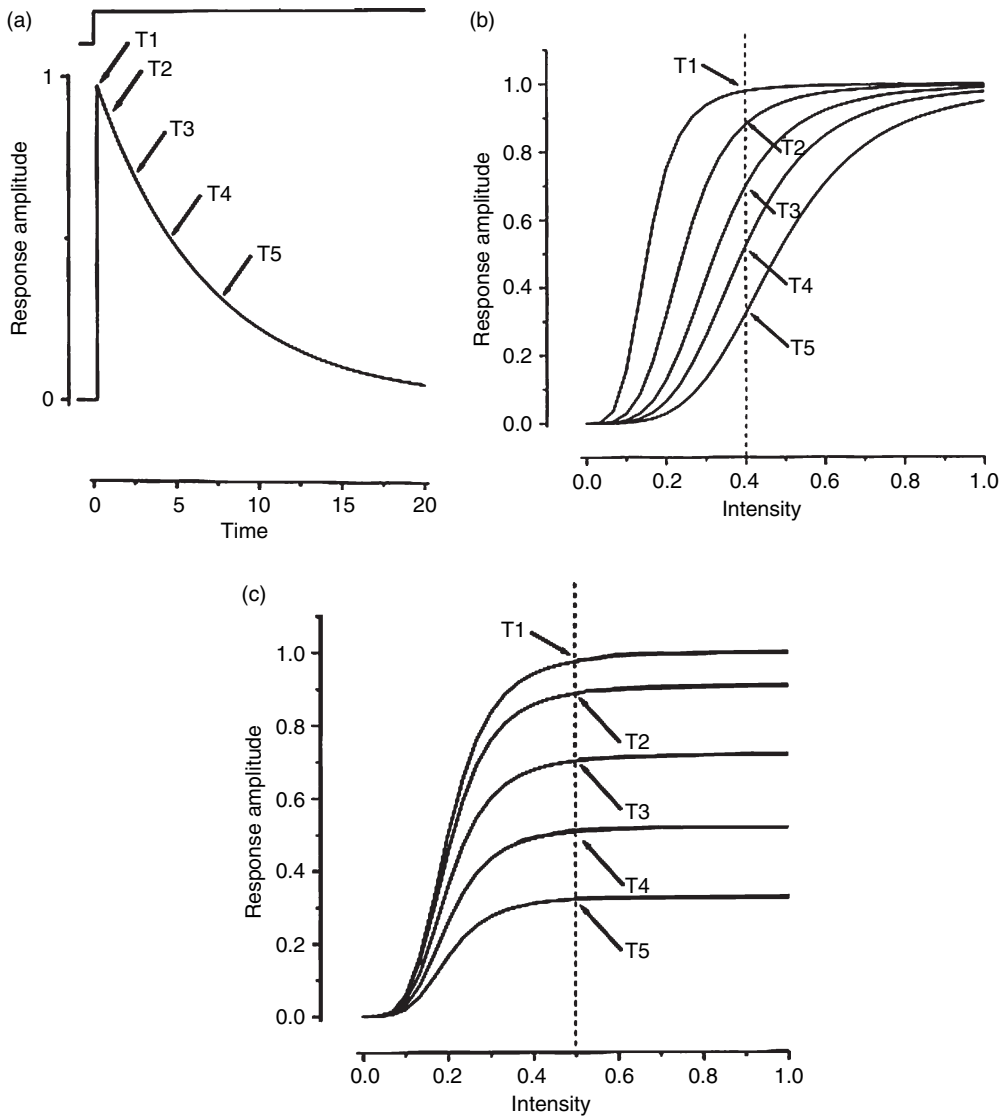

Figure 7 Response decay explained by either the change in $K_{1/2}$ (b) or change in I_{max} (c). (a) Time course of the odorant-induced current. (b) Gradual change of the dose–response relation accompanying the increase of $K_{1/2}$. (c) Gradual change of the dose–response relation accompanying the reduction of I_{max}.

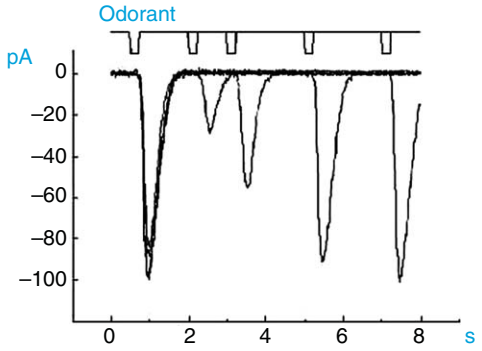

Figure 8 Adaptation and recovery of single ORC responses. Note that the amplitude of the secondary responses is reduced in size. This current reduction is attributable to the change in the dose–response relation as in Figure 9. As the inter-interval is increased, the current amplitude returns to the initial level. Complete recovery is observed after *c*. 10 s.

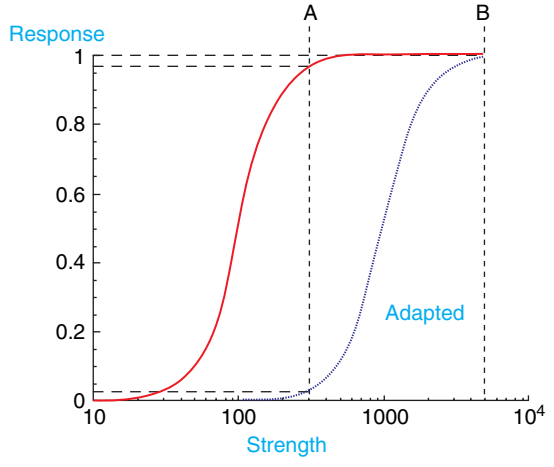

Figure 9 Contribution of sensory adaptation on establishing a wide dynamic range. Dose–response relation is shifted in order to expand the dynamic range. Under the standard condition (red curve), the ORC cannot discriminate the change in the stimulus strength between A and B. In the adapted state (blue, dashed line), A and B can be discriminated as a difference in the response amplitude.

cover a wider range for the stimulus strength. As illustrated in Figure 9, shift of the dose–response curve (change in $K_{1/2}$) can establish two competitive functions; signal amplification and wide dynamic range. In contrast, desensitization or fatigue during a long step includes all decaying phenomena. For instance, change in the I_{max} can also express the same phenomenon, but in this case, the dynamic range is not changed (Figures 7(b) and 7(c)).

The ORC itself has an ability of adaptation. This sensory adaptation is achieved in the ciliary molecular circuit that utilizes the Ca^{2+} movement through the CNG channel. Influx of Ca^{2+} causes an increase in the cytoplasmic Ca^{2+} concentration. Cytoplasmic Ca^{2+} binds to the CAM that has already attached to the CAM-binging domain locating N-terminal cytoplasmic chain of the CNG channel. This causes reduction of the ligand affinity leading to the change of the total sensitivity. In contrast, mechanisms causing olfactory fatigue are still not yet well identified.

Ca ions that flowed through the CNG channels play crucial roles in the ORCs as described (activation of Cl^- and K^+ channel, regulation for adaptation). This Ca^{2+} must be excluded from the cilia. Unfortunately, at this moment, there is little information about the Ca^{2+} extrusion system. Electrophysiological data show that Ca^{2+} extrusion mechanism in the olfactory sensory cilia is dependent on the presence of external Na^+. As a homologous biological system, photoreceptor outer segment is equipped with Na/Ca/K exchanger that regulates cytoplasmic Ca^{2+} level. There is a possibility that the same molecular element is present in the olfactory sensory cilia (for detail, see Matthews, H. R. and Reisert, J., 2003).

4.28.11 Functional Roles of Molecular Elements in the Olfactory Cilia

As described, the molecular network within the sensory cilia establishes an elegant and sophisticated signal processing. Active time courses of the molecular elements were investigated by the series of works done by Takeuchi H. and Kurahashi T. (2002; 2003; 2005), in which odorant-induced response and cAMP-induced response were directly compared in the living olfactory cilia (Figure 10).

Very short lifetime of the active odorant receptor is extended while the signal is transmitted to G_{olf} and AC (Figure 11). cAMP molecules survives longer than the active time of AC, until they are hydrolyzed by the activity of PDE. In addition, cytoplasmic Ca^{2+} may be kept for some period of time, until Ca^{2+}-binding proteins trap them or until they are excluded. These time courses of cytoplasmic factors will further extend the active time for the signals.

During the active lifetime of cAMP, CNG channels are kept open, which allows Ca^{2+} to enter into the cytoplasm. This Ca^{2+} opens Ca^{2+}-activated Cl^- channels. At this stage, the signal amplitude is boosted in a nonlinear manner. A long step of odorant

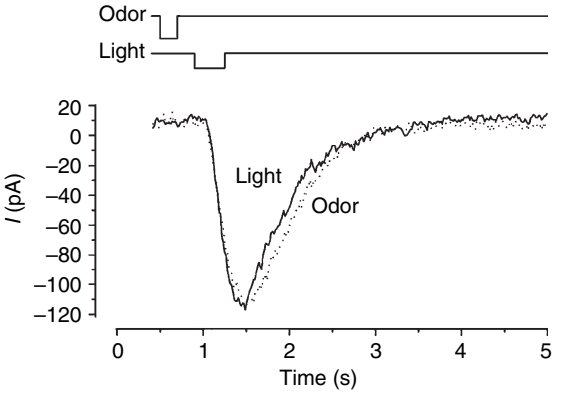

Figure 10 Estimation of odor-activated AC activity by a response-clamp experiment. Cytoplasmic cyclic nucleotide (cGMP having the same effect as cAMP) was increased by photolysis of cytoplasmic caged cGMP. The light condition was adjusted to induce an identical waveform of response as the odorant response. In this experimental condition, the period of light exposure is comparable to the activation of odorant-induced AC activity. Note that the light exposure is delayed from the odorant stimulation and that the period is longer. Also, the current response lasts longer than the light exposure. This indicates that cytoplasmic elements (cAMP and/or Ca^{2+}) remain longer than the AC activity. From Takeuchi, H. and Kurahashi, T. 2002. Photolysis of caged cyclic AMP in the ciliary cytoplasm of the newt olfactory receptor cell. J. Physiol. (Lond.) 541(Pt 3), 825–833.

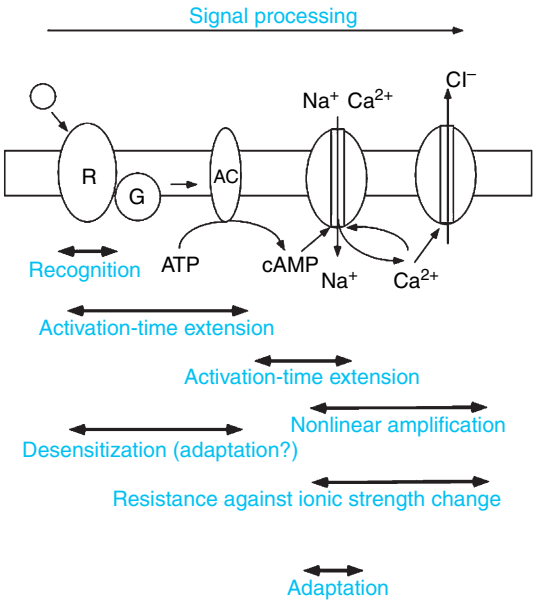

Figure 11 Functional roles of olfactory molecular elements.

stimulation causes gradual increase of cAMP production rate, and $[cAMP]_i$ increases superlinearly with time for over a second. Therefore, the rising phase of the response becomes very rapid and instantaneous.

The combination of cation and anion components is also important for the resistance against the change in the external ionic strength. Having both ion channels together, any change in the cationic current accompanied with the change in the NaCl concentration can be compensated by the inverse stream of the anions.

Adaptation is regulated by the Ca^{2+}-feedback to the CNG channel where very high nonlinear amplification is established. In addition, there is a possibility that desensitization is also regulated at the upstream point from the AC. These molecular roles are summarized in Figure 11.

4.28.12 Resting Membrane Potential and Spike Discharges

As has been generally known for neurons, the olfactory cell is equipped with an excitatory membrane having several types of voltage-gated ion channel. Most of them are distributed in the interstitial area (dendrosomatic regions) of the ORC. As described, the resting potential of the ORC is about −50 to −70 mV. This value is close to the equilibrium potential for the K ions, and it is therefore likely that the resting potential is determined by the K-dominant component. In case of rodents, an ionic channel that is activated by the hyperpolarization (I_h channel) seems to be involved in the determination of the resting potential. Since I_h channels have permeability to both Na^+ and K^+, the resting potential of these cells may be a bit depolarized. This may provide an important function that the resting potential is closed to the spike-firing threshold. However, such I_h channels are not observed in amphibian. Because of this, amphibian ORCs have very high input resistance (>5 GΩ). Such high input resistance would be remarkable especially at the hyperpolarizing voltage region. It may be possible to think that inhibitory responses (presumably evoked by the Ca^{2+}-activated K^+ channels) are dominant for the amphibian.

For the spike discharges, voltage-dependent Na^+ and Ca^{2+} channels have been shown to be involved in their generations. Essentially, Na^+ channel is a major element that is needed for the spike generation, and Ca^{2+} channel (especially T-type) has an ability of lowering the threshold. The falling phase is shaped by the action of K^+ channel (delayed rectifier and transient K^+ channels) (Table 1).

Table 1 Ionic channels equipped in the olfactory receptor cell

	Functions
Transduction channels	
CNG channel	Initiation of membrane excitation
Ca^{2+}-activated Cl^- channel	Boosting the transduction current
Ca^{2+}-activated K^+ channel	Inhibitory response (?)
$InsP_3$-gated channel	Parallel transduction pathway (?)
Voltage-dependent channels	
Na^+ channel	Initiation of spikes
L-type Ca^{2+} channel	Ca^{2+} uptake, generation of spike
T-type Ca^{2+} channel	Lowering the spike threshold
Delayed K^+ channel	Sharpen the spike falling phase
Transient K^+ channel (A channel)	Sharpen the spike falling phase Repetitive spikes (re-activation of Na)
Ca^{2+}-activated K^+ channel	Resting membrane potential Spike falling phase
Hyperpolarization-activated cation (h) channel (rodents)	Resting membrane potential

4.28.13 Modulation of Membrane Excitability of the Olfactory Receptor Cell

As described, the ORC is the entrance for the olfactory sensation. It is likely that this step is controlled by a number of endocrine factors. First observation was that adrenalin changed spike initiation patterns by modulating activities of voltage-gated Na^+ and Ca^{2+} channels via an ATP-dependent protein kinase. Besides, dopamine, Ach, serotonin, and LHRH have been shown to modulate the activities of ORCs (for details; see bibliography by Narusuye, K. *et al.*, 2003 and related articles). These findings raise a possibility that the olfactory input is changed depending on the physical and emotional status. In the psychological works, there are cumulative data showing that the olfactory sensation is strongly influenced by the body condition. It is highly expected that in near future the modulatory effects by endocrine factors on ORCs are correlated with the human olfactory sensations.

4.29.1 Introduction

Nakamura T. and Gold G. H. (1987) using excised patches of cilia membrane from olfactory neurons recorded macroscopic ionic currents directly activated by cAMP. The ion channel responsible for this conductance has since then been cloned and identified in several species (Kaupp, U. B. and Seifert, R., 2002). Cyclic nucleotide-gated (CNG) channels form a family of ion channels that are structurally related to voltage-gated channels (Figure 1). They require the binding of at least two cyclic nucleotide molecules for activation (Zufall, F. *et al.*, 1991; Biskup, C. *et al.*, 2007). Although they have recently been identified in an assortment of cell types and tissues, they are most prevalent in the peripheral sensory receptor cells of the visual and olfactory systems (Kaupp, U. B. and Seifert, R., 2002; Pifferi, S. *et al.*, 2006). In olfactory neurons, these channels can be activated by either cAMP ($K_d = 20\,\mu M$) or cGMP ($K_d = 5\,\mu M$), although it is generally believed that under normal physiological conditions it is a rise in intracellular cAMP that is responsible for channel activation (Firestein, S. and Zufall, F., 1994; Shepherd, G. M., 1994). A high density of CNG channels is present on the ciliary membrane of olfactory neurons. These channels are selective for cations, and their activation leads to cell membrane depolarization. Native CNG channels are known to be permeable to Ca^{2+} ions, but because the Ca^{2+} ions bind to sites on their way through the pore they also act to block monovalent currents (Frings, S. *et al.*, 1995; Zagotta, W. N. and Siegelbaum, S. A., 1996).

4.29.2 Phylogeny

In vertebrates, six members of the CNG channel gene family have been identified. These genes are grouped according to sequence similarity into two subtypes, CNGA and CNGB (Bradley, J. *et al.*, 2001a). Additional genes coding for CNG channels have been cloned from *Drosophila melanogaster* and *Caenorhabditis elegans*. The phylogenetic relationship of these channels is shown in Figure 2.

The first cDNA clone for a subunit of a CNG channel, CNGA1 (previously called α1, CNG1 or RCNC1) has been isolated from bovine retina (Kaupp, U. B. *et al.*, 1989). CNGA1 is expressed in rod photoreceptors and produces functional channels that are gated by cGMP when expressed exogenously either in *Xenopus* oocytes or in a human embryonic kidney cell line (HEK293). Mutations in CNGA1 in humans cause an autosomal recessive form of retinitis pigmentosa, a degenerative form of blindness (Dryja, T. P. *et al.*, 1995). Later, the second subunit of the rod channel, CNGB1 (previously called β_1 CNG4 or RCNC2), has been isolated and cloned (Chen, T.-Y. *et al.*, 1993; Korschen, H. G. *et al.*, 1995). CNGB1 subunits expressed alone do not produce functional CNG channels, but coexpression of CNGA1 and CNGB1 subunits yields heteromeric channels with permeation, modulation, pharmacology, and cyclic-nucleotide specificity similar to that of native channels (Chen, T.-Y. *et al.*, 1993; Korschen, H. G. *et al.*, 1995). CNG channels form tetrameric

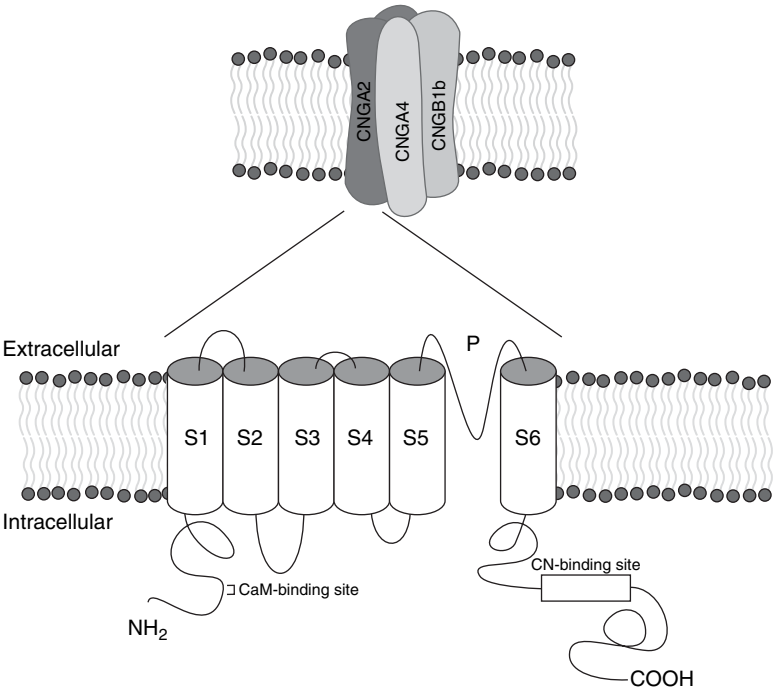

Figure 1 Tetrameric model of an olfactory CNG channel comprising two CNGA2, one CNGA4, and one CNGB1b subunits. A schematic representation of the two-dimensional architecture of one CNG channel subunit is also shown. S1–S6 are the putative transmembrane domains and P is the putative pore region. The cyclic nucleotide (CN)-binding site is defined by homology to the sequences of cAMP and cGMP binding proteins. The position of the Ca^{2+}-calmodulin (CaM) binding site is indicated for an olfactory CNGA2 subunit.

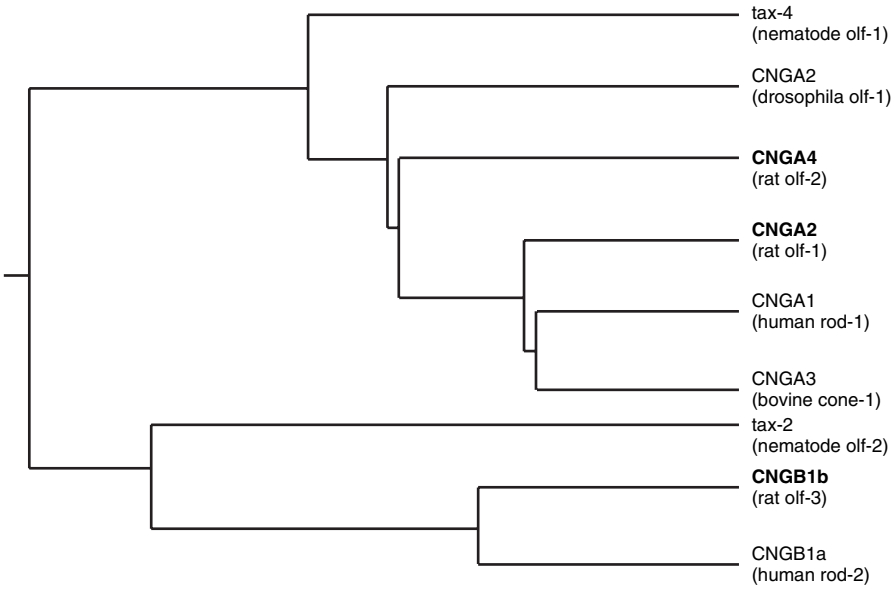

Figure 2 Phylogenetic tree of the olfactory and retinal CNG channels subunits. The tree was calculated on the basis of the sequence alignments with the transmembrane domains and the cyclic nucleotide binding site of the respective subunits.

molecules (Varnum, M. D. *et al.*, 1995; Gordon, S. E. and Zagotta, W. N., 1995b; Liu, D. T. *et al.*, 1996) with a stoichiometry of three CNGA1 subunits and one CNGB1 subunit (Weitz, D. *et al.*, 2002; Zheng, J. *et al.*, 2002; Zhong, H. *et al.*, 2002).

The CNG channels from cone photoreceptors are composed of two other types of subunits, CNGA3 (previously called $\alpha 2$, CNG3 or CCNC1) and CNGB3 (previously called $\beta 2$, CNG6 or CCNC2) (Bonigk, W. *et al.*, 1993; Gerstner, A. *et al.*, 2000) with a stoichiometry of two CNGA3 and two CNGB3 (Peng, C. *et al.*, 2004). CNGA3 subunits, but not CNGB3 subunits, form functional channels when expressed in heterologous systems. Mutations in human CNGA3 and CNGB3 have been linked to complete achromatopsia (also referred to as rod monochromacy or total color blindness), a rare, autosomal recessive inherited and congenital disorder characterized by the complete inability to discriminate between colors (Kohl, S. *et al.*, 1998; Sundin, O. H. *et al.*, 2000; Wissinger, B. *et al.*, 2001).

Native olfactory CNG channels are constructed from three different but highly homologous subunits (Figure 1), the CNGA2 (previously called $\alpha 3$, CNG2 or OCNC1) (Dhallan, R. S. *et al.*, 1990), the CNGA4 (previously called $\alpha 4$, CNG5 or OCNC2) (Bradley, J. *et al.*, 1994; Liman, E. R. and Buck, L. B., 1994), and the CNGB1b (previously called $\beta 1$, CNG4.3 or RCNC2) (Sautter, A. *et al.*, 1998; Bonigk, W. *et al.*, 1999) subunits. The stoichiometry of olfactory CNG channels has been identified using fluorescently tagged subunits and fluorescence resonance energy transfer (Zheng, J. and Zagotta, W. N., 2004). They are tetrameric molecules composed of two CNGA2, one CNGA4 and one CNGB1b subunits. The CNGA2 subunits form cAMP-activated channels when heterologously expressed in mammalian cells (Dhallan, R. S. *et al.*, 1990). This conductance is less sensitive to cAMP than the native rat channel and shows very little rectification in the absence of divalent cations, whereas the native CNG conductance is outward rectifying in the presence of physiological calcium concentration (Frings, S. *et al.*, 1992; Bonigk, W. *et al.*, 1999). The second olfactory subunit cloned (CNGA4) is 52% identical to the CNGA2 (Bradley, J. *et al.*, 1994; Liman, E. R. and Buck, L. B., 1994). The expression of CNGA4 alone in *Xenopus* oocytes or its transfection into HEK293 cells shows no activation by cyclic nucleotides (Bradley, J. *et al.*, 1994; Liman, E. R. and Buck, L. B., 1994). When the CNGA2 and the CNGA4 are coexpressed in mammalian cells (Bradley, J. *et al.*, 1994) or *Xenopus* oocytes (Liman, E. R. and Buck, L. B., 1994), an outward rectifying cation conductance exhibiting a cAMP sensitivity closer to the native CNG channel is observed. The third subunit of the olfactory CNG channel, the CNGB1b (Sautter, A. *et al.*, 1998; Bonigk, W. *et al.*, 1999), is a spliced form of the rod photoreceptor CNGB1a subunit. When this subunit is coexpressed with the CNGA2 and CNGA4 subunit in HEK293 cells, it creates channels with sensitivity for cAMP, discrimination between Na^+ and K^+, single-channel conductance, kinetics of open–closed transitions and the presence of subconductance states similar to the native olfactory channel.

Two extra CNG channel subunits have been identified in *D. melanogaster*. The first one is expressed in the antennae and in the visual system, suggesting that CNG channels may be involved in the transduction of light in invertebrates (Baumann, A. *et al.*, 1994) and the second, a putative CNG-like channel subunit, is expressed in the brain (Miyazu, M. *et al.*, 2000). Two CNG channel subunits, Tax-2 and Tax-4, have also been cloned in *C. elegans* (Coburn, C. M. and Bargmann, C. I., 1996; Komatsu, H. *et al.*, 1996); they are required for chemosensation, thermosensation, and normal axon outgrowth of sensory neurons.

4.29.3 Structure

CNG channels are composed of four subunits around a centrally located pore (Gordon, S. E. and Zagotta, W. N., 1995b; Liu, D. T. *et al.*, 1996; Varnum, M. D. and Zagotta, W. N., 1996). Each subunit contains six transmembrane segments, a reentrant P-loop and intracellular amino- and carboxy-terminal regions (Figure 1) (Kaupp, U. B. *et al.*, 1989; Molday, R. S. *et al.*, 1991; Wohlfart, P. *et al.*, 1992; Liu, D. T. *et al.*, 1996). The P-loop and the S6 segment line the ion-conducting pore. The carboxy-terminal region contains a cyclic nucleotide (CN)-binding site and a region connecting it to the S6 segment (the C-linker region). The amino-terminal region and the region following the CN-binding domain have specialized functions for each of the CNG channel subtypes. A series of elegant experiments with cloned channels and chimeric constructs have identified several regions as well as specific residues distributed, in particular, throughout the approximately 500 amino acids of the CNGA1 (retinal) or the CNGA2 (olfactory) subunit proteins that play a key role in channel regulation (Matulef, K. and Zagotta, W. N., 2003). The characteristics of these regions will be discussed below.

4.29.3.1 Pore

The pore region of the channel controls both the single-channel conductance and the pore diameter of the channel (Goulding, E. H. *et al.*, 1993). The determination of how ions permeate the channel and how the ionic selectivity occurs is of great physiological importance because ion permeation is responsible for generating membrane depolarization which is critical for electrical signaling, but also the CNG channels are permeable to Ca^{2+} which is an important element in the activation of intracellular targets. Balasubramanian S. *et al.* (1997) have demonstrated that the permeation properties of the olfactory CNG channels are significantly different from those of photoreceptor CNG channels. Their results further indicate that Na^{+} currents through these channels do not obey the independence principle and show saturation kinetics with K(m)s in the range of 100–150 mM. They also display a lack of voltage dependence of conductance in asymmetric solutions that suggests that ion-binding sites are situated midway along the channel pore.

Wells G. B. and Tanaka J. C. (1997) have developed a two-site, Eyring rate theory model of ionic permeation for CNG channels. The parameters of the model are optimized by simultaneously fitting current–voltage data sets from excised photoreceptor patches in electrolyte solutions containing one or more of the following ions: Na^{+}, Ca^{2+}, Mg^{2+}, and K^{+}. The model accounts well for the shape of the IV relations, the binding affinity for Na^{+}, the reversal potential values with single-sided additions of calcium or magnesium and biionic KCl, and the $K_{1/2}$ and voltage dependence for divalent block from the cytoplasmic side of the channel. The differences between the predicted $K_{1/2}$s for extracellular block by Ca^{2+} and Mg^{2+} and the values obtained from heterologous expression of only the CNGA1 subunit of the channel suggest that the CNGB1 subunit or a cell-specific factor affects the interaction of divalent cations at the external but not the internal face of the channel. The model predicts concentration-dependent permeability ratios with single-sided addition of calcium and magnesium and anomalous mole fraction effects under a limited set of conditions for both monovalent and divalent cations. Calcium and magnesium are predicted to carry 21 and 10%, respectively, of the total current in the retinal rod cell at −60 mV.

In addition to permeating the CNG channel, Ca^{2+} also profoundly blocks the current flow carried by monovalent cations through the channels (Zagotta, W. N. and Siegelbaum, S. A., 1996) similar to the behavior observed in voltage-activated Ca^{2+}-channels (Almers, W. and McCleskey, E. W., 1984). Supposedly, this behavior implies the high-affinity binding of Ca^{2+} to a single acidic amino acid residue located in the pore of the channel (E363 for the rod CNG channel and E333 for the catfish olfactory CNG channel) (Root, M. J. and MacKinnon, R., 1993). These authors have also implicated this particular glutamate residue as being important in the external rapid proton block of CNG channels, another characteristic that the CNG channels share with Ca^{2+} channels. Gavazzo P. *et al.* (1997) have examined the modulation by internal protons of the bovine CNGA1 and CNGA2 subunits. Increasing internal proton concentrations causes a partial blockage of the single-channel current, consistent with protonation of a single acidic site with a pK1 of 4.5–4.7, both in rod and in olfactory CNG channels. Channel gating properties are also affected by internal protons. The open probability at low cyclic nucleotide concentrations is greatly increased by lowering pH_i, and the increase is larger when channels are activated by cAMP than by cGMP. Therefore, internal protons affect both channel permeation and gating properties, causing a reduction in single-channel current and an increase in open probability. These effects are likely to be caused by different titratable groups on the channel.

Amino acid conservation among a wide range of P-loop-containing channels suggests that the structures of the KcsA, a bacterial potassium channel (Doyle, D. A. *et al.*, 1998), and of the MthK, another channel (Jiang, Y. *et al.*, 2002a; 2002b), may serve as general models for the closed and open state conformations of CNG channels. Experimental evidence using cysteine mutations suggests that the cytoplasmic opening of the CNG channel pore is narrow when channels are closed and widens when channels open (Flynn, G. E. and Zagotta, W. N., 2001). Cysteine-scanning mutagenesis studies suggest that the pore helix, near the selectivity filter, undergoes a conformational change during channel activation (Becchetti, A. *et al.*, 1999; Liu, J. and Siegelbaum, S. A., 2000). Recently, site-directed mutagenesis and inside-out patch-clamp recordings (Qu, W. *et al.*, 2006) have been used to investigate ion permeation and selectivity of the rat CNGA2 channels expressed in HEK293 cells. A single point mutation of the negatively charged P-loop glutamate (E342) to either a positively charged lysine or

arginine has resulted in functional channels, which consistently respond to cGMP, although the currents are generally extremely small. These results show that it is predominantly the charge of the E342 residue in the P-loop that controls the cation–anion selectivity of this channel. These results also have potential implications for the determinants of anion–cation selectivity in the large family of P-loop-containing channels.

4.29.3.2 Cyclic Nucleotide-Binding Domain

Since the demonstration by Fesenko E. E. *et al.* (1985) and Nakamura T. and Gold G. H. *et al.* (1987) that CNG channels could be directly activated by intracellular cyclic nucleotides, a highly conserved stretch of approximately 120 amino acids homologous to the CN-binding domains of other proteins like the cAMP or cGMP protein kinases has been identified. It consists of a short amino-terminal α helix preceding an eight-stranded anti-parallel β roll that is followed by two α helices (Zagotta, W. N. and Siegelbaum, S. A., 1996). A structural model of the retinal CNG channel CN-binding site has also been constructed (Kumar, V. D. and Weber, I. T., 1992).

The retinal and olfactory CNG channels share a high degree of sequence similarity (over 80% amino acids identity) in the CN-binding sites, but they have very different cyclic nucleotide selectivities. cGMP is a more potent and effective agonist of the retinal channel (Fesenko, E. E. *et al.*, 1985) while cAMP and cGMP have very similar effects on the olfactory channel (Zufall, F. *et al.*, 1994). Varnum M. D. *et al.* (1995) have investigated the molecular mechanism for ligand discrimination of CNG channels. They have found that the retinal photoreceptors and olfactory neurons CNG channels are differentially activated by ligands that varied only in their purine ring structure. The nucleotide selectivity of the retinal bovine CNG channel (cGMP > cIMP $\gg$ cAMP) is significantly altered by neutralization of a single aspartic acid residue (D604) in the CN-binding site (cGMP $\geq$ cAMP > cIMP). Substitution by a nonpolar residue at this position inverts agonist selectivity (cAMP $\gg$ cIMP $\geq$ cGMP). These effects result from an alteration in the relative ability of the agonists to promote the allosteric conformational change associated with channel activation, not from a modification in their initial binding affinity. These authors propose a general mechanism for guanine nucleotide discrimination, in common with that observed in high-affinity GTP-binding proteins, involving the formation of a pair of hydrogen bonds between the aspartic acid side chain and N1 and N2 of the guanine ring. This amino acid residue (D604) appears to play a critical role in the selective activation of the retinal CNG channel by cGMP. The presence of a methionine at this position in CNGA4 is sufficient to explain the altered ligand specificity of the native olfactory channel (Shapiro, M. S. and Zagotta, W. N., 2000).

The functional effects of each ligand-binding event have always been difficult to assess because ligands continuously bind and unbind at each site. Furthermore, in retinal rod photoreceptors, the low cytoplasmic concentration of cyclic GMP means that CNG channels exist primarily in partially liganded states. Ruiz M. L. and Karpen J. W. (1997) have studied single CNG channel behavior with the use of a photoaffinity analogue of cGMP that tethered cGMP moieties covalently to their binding sites to show that single retinal CNG channels could be effectively locked in four distinct ligand-bound states. Their results indicate that CNG channels open more than they would spontaneously when two ligands are bound (approximately 1% of the maximum current), significantly more with three ligands bound (approximately 33%), and open maximally with four ligands bound. In each ligand-bound state, channels open to two or three different conductance states. These findings place strong constraints on the activation mechanism of CNG channels.

This issue has been investigated further by Liu D. T. *et al.* (1998). These authors observe the effects of individual binding events on channel activation by studying CNG channels containing one, two, three, or four functional CN-binding sites. They find that the binding of a single ligand significantly increases channel opening, although four ligands are required for full channel activation. Their data are inconsistent with models in which the four subunits activate in a single concerted step (Monod-Wyman-Changeux model) or in four independent steps (Hodgkin-Huxley model). Instead, the four subunits of the channel may associate and activate as two independent channel dimers.

A molecular mechanism for the conformational changes that occur in the ligand-binding domain during channel activation has been proposed (Varnum, M. D. *et al.*, 1995). In this mechanism, the CN initially binds to the closed channel primarily by interactions between the β roll and the ribose and cyclic phosphate of the CN. CN binding is followed by a conformational change in the CN-

binding site that is coupled to the opening of the pore. This conformational change in the CN-binding site is proposed to involve a relative movement of the C-helices toward the β rolls of each subunit, allowing the D604 residues to interact with the purine rings of the bound CN. This interaction could provide a significant portion of the energy required to drive an otherwise unfavorable opening conformational change. This mechanism is supported by additional experiments. Mutation in the β roll of R559, the residue that forms the primary salt bridge with the phosphate of the CN, dramatically inhibits the initial binding of ligand, decreasing the apparent affinity of the channel for cAMP and cGMP (Tibbs, G. R. *et al.*, 1998). Furthermore, cysteine modification of C505 in the β roll primarily affects the initial binding of cGMP, whereas modification of an introduced cysteine in the C-helix, G597C, primarily affects the agonist potency (Matulef, K. *et al.*, 1999). It has been shown that cysteine residues in the C-helix produce an intersubunit disulfide bond primarily when the channel is closed (Matulef, K. and Zagotta, W., 2002; Mazzolini, M. *et al.*, 2002), suggesting that the C-helices might be nearer to each other or more flexible in the closed state of the channel and separate upon opening. It is still not known how the binding of the ligands to the channel subunits is translated into channel opening. The activation of olfactory CNG channels has been studied further by photolysis-induced jumps of cGMP or cAMP (Nache, V. *et al.*, 2005) and found to be highly cooperative. A model containing three highly cooperative binding sites with a ligand affinity high–low–high described their experimental data most adequately. Recently, Biskup C. *et al.* (2007) have studied homomeric CNGA2 channels in inside-out membrane patches by simultaneously determining channel activation and ligand binding, using the fluorescent cGMP analogue 8-DY547-cGMP as the ligand. They have shown that four ligands bind to the channels and that there is significant interaction between the binding sites. Among the binding steps, the second is most critical for channel opening: its association constant is three orders of magnitude smaller than the others and it triggers a switch from a mostly closed to a maximally open state. These results contribute to unraveling the role of the subunits in the cooperative mechanism of CNGA2 channel activation and could be of general relevance for the activation of other ion channels and receptors.

4.29.3.3 C-Linker region

The CN-binding site is connected to the last transmembrane segment of the channel by a chain of approximately 90 amino acids known as the C-linker region. Experimental evidences suggest that the N-terminal region of the channel and the C-linker region influence the apparent agonist affinity and efficacy with which the cyclic nucleotides open the channel. The C-linker region has been implicated by several studies as being critical in the gating reaction that leads to channel activation subsequent to CN binding.

As a first attempt toward understanding the channel-gating process, Gordon S. E. and Zagotta W. N. (1995a) have studied the mechanism of potentiation of expressed rod CNG channels by Ni^{2+}. They have found that coordination binding of Ni^{2+} between histidine residues (H420) on adjacent channel subunits occurs when the channels are open. Mutation of H420 to lysine completely eliminates the potentiation by Ni^{2+} but does not markedly alter the apparent cGMP affinity of the channel, indicating that the introduction of positive charge at the Ni^{2+}-binding site is not sufficient to produce potentiation. Deletion or mutation of most of the other histidines present in the channel do not diminish Ni^{2+} potentiation. These authors have also examined the role of subunit interactions in Ni^{2+} potentiation by generating heteromultimeric channels using dimers of the rod CNG channel. Injection of single heterodimers (wt/H420Q or H420Q/wt) in which one subunit contains H420 and the other does not resulted in channels that are not potentiated by Ni^{2+}. However, coinjection of both heterodimers into *Xenopus* oocytes results in channels that exhibit potentiation. The H420 residues probably occurs predominantly in nonadjacent subunits when each heterodimer is injected individually, but when the two heterodimers are coinjected, the H420 residues could occur in adjacent subunits as well. Their results suggest that the mechanism of Ni^{2+} potentiation involves intersubunit coordination of Ni^{2+} by H420. Based on the preferential binding of Ni^{2+} to open channels, they suggest that alignment of H420 residues of neighboring subunits into the Ni^{2+}-coordinating position may be associated with channel opening. These authors have also identified the corresponding histidine residue on olfactory CNGA2 subunits (H396) to have an opposite effect, an inhibition, on Ni^{2+} binding (Gordon, S. E. and Zagotta, W. N., 1995c). Thus, this particular C-linker

region of the channel probably undergoes a movement during the opening transition (Gordon, S. E. and Zagotta, W. N., 1995a; 1995b). Indeed, a histidine scan of the region just below the S6 in CNGA1 channels has found that histidines introduced at positions 416 and 420 caused Ni^{2+} to stabilize the open state (Johnson, J. P., Jr. and Zagotta, W. N., 2001). The state dependence of Ni^{2+} coordination suggests a model in which a translation and clockwise rotation of this region relative to the central axis of the pore are involved in channel activation.

The cone and olfactory CNG channels also differ considerably in cyclic nucleotide affinity and efficacy. Zong X. *et al.* (1998) have found that three amino acids in the C-linker region are major determinants of gating in these CNG channels. Indeed, the replacement of three amino acids in the cone C-linker by the corresponding amino acids of the olfactory channel (I439V, D481A, and D494S) profoundly enhances the cAMP efficacy and increases the affinities for cAMP and cGMP. Unlike the wild-type cone channel, the mutated channel exhibits similar (olfactory) single-channel kinetics for both cGMP and cAMP, explaining the increase in cAMP efficacy. Therefore, the identified amino acids appear to be major determinants of CNG channel gating.

Among the other key amino acid residues of the C-terminal end of the channel are a series of intracellularly located cysteine residues in or near the CN-binding site (Biel, M. *et al.*, 1996). These residues are thought to affect the gating reaction either through subunit–subunit interactions or within single subunits (Varnum, M. D. and Zagotta, W. N., 1996; Gordon, S. E. *et al.*, 1997). At least one of those cysteines has been proposed as a site which undergoes redox modulation by reactive nitrogen species *via* S-nitrosylation. Indeed, biochemical experiments allowed Broillet M.-C. and Firestein S. (1996) to find that the cysteine in position C460 in the CNGA2 subunit of the rat is the critical residue in the reaction that leads to channel activation by nitric oxide (NO). This particular cysteine residue is located within the C-linker region just N-terminal to the CN-binding site.

Brown L. A. *et al.* (1998) have probed the structural changes that occur during channel activation by CN using SH-modifying reagents on the bovine CNGA1 subunit. Treatment with these reagents dramatically potentiates the channel's response to both cAMP and cGMP. This potentiation is abolished by conversion of the cysteine residue C481 to a nonreactive alanine residue. Potentiation occurs more rapidly in the presence of saturating cGMP, indicating that this region of the channel is more accessible when the channel is open. C481 is located in the C-linker region between the S6 transmembrane domain and CN-binding site and corresponds to the C460 residue of the olfactory channel which is the NO target site. These results suggest that this region of the channel undergoes significant movement during the activation process and is critical for coupling ligand binding to pore opening. Brown L. A. *et al.* (1998) also claim that potentiation, however, is not mediated by the recently reported interaction between the amino- and carboxy-terminal regions of the CNGA1 subunit because deletion of the entire amino-terminal domain had little effect on potentiation by SH-modifying reagents.

Other parts of the C-linker have also been found to affect the allosteric opening transition. The *C. elegans* TAX-4 channel has a much higher cyclic nucleotide efficacy and sensitivity than the bovine CNGA1 channel (Komatsu, H. *et al.*, 1996; Paoletti, P. *et al.*, 1999). These differences are largely due to three residues in the C-linker, R460, I465, and N466 (numbers correspond to CNGA1 channels) (Paoletti, P. *et al.*, 1999). In addition, differences between gating of CNGA3 and CNGA2 channels have been attributed to three amino acids in the C-linker (I415, D457, and D470) (Zong, X. *et al.*, 1998). Also, protons bind to H468 in CNGA1 channels, causing a potentiation similar to that caused by Ni^{2+} (Gordon, S. E. *et al.*, 1996). Another residue in the C-linker near the beginning of the CNBD, C481, undergoes state-dependent modification by the cysteine-modifying reagents *N*-ethylmaleimide and methanethiosulfonate-ethyltrimethylammonium (Gordon, S. E. *et al.*, 1997; Brown, L. A. *et al.*, 1998). A fluorophore attached to this site has also been shown to undergo state-dependent quenching (Zheng, J. and Zagotta, W. N., 2000). These studies suggest that the entire C-linker region may be involved in the allosteric opening transition.

4.29.3.4 Amino-Terminal Domain

The amino-terminal region of some CNG channels has been found to affect the allosteric opening transition. CNGA2 channels have a lower free energy of opening compared with that of CNGA1 channels (Goulding, E. H. *et al.*, 1994; Liu, M. *et al.*, 1994; Gordon, S. E. *et al.*, 1995b; Fodor, A. A. *et al.*, 1997). Replacing the amino-terminal domain of CNGA1 with that of CNGA2 decreases the free energy of opening, whereas replacing the amino-terminal domain of CNGA2 with that of CNGA1 increases the free energy

of opening (Goulding, E. H. *et al.*, 1994; Gordon, S. E. *et al.*, 1995b). Single-channel analysis shows that the CNGA2 amino terminus stabilizes the open state, causing a dramatic increase in the open probability for partial agonists such as cAMP (Sunderman, E. R. and Zagotta, W. N., 1999). Deleting part of the CNGA2 amino-terminal region decreases the open probability for cAMP and the apparent affinity for cGMP, suggesting that this region has an autoexcitatory effect on channel gating (Liu, M. *et al.*, 1994).

Using polypeptides expressed in bacteria, the amino- and carboxy-terminal regions of CNGA2 have been found to interact directly (Varnum, M. D. and Zagotta, W. N., 1997). Furthermore, this interaction can be blocked by the addition of Ca^{2+}-calmodulin, not by the addition of either Ca^{2+} or calmodulin alone (Varnum, M. D. and Zagotta, W. N., 1997) leading to a proposed mechanism for Ca^{2+}-calmodulin modulation in which the CNGA2 amino-terminal domain has an autoexcitatory effect by interacting with the CNGA2 carboxy-terminal domain, and Ca^{2+}-calmodulin inhibits CNGA2 channels by preventing this interaction.

4.29.4 Physiology

One important model system to study the different functions of CNG channels is the olfactory system (Firestein, S. and Zufall, F., 1994). The remarkable capacity to discriminate among a wide range of odor molecules begins at the level of the olfactory sensory neurons (OSNs). These particular neurons perform the complex task of converting the chemical information contained in the odor molecules into changes in membrane potential (Shepherd, G. M., 1994). The different steps of the transduction cascade (Figure 3) can be summarized as follows: when a receptor molecule is occupied by an odorant, it activates a specific GTP-binding protein (G_{olf}), which modulates the activity of an adenylyl cyclase (AC type III), an enzyme producing the second messenger cAMP. cAMP directly activates a CNG channel representing the first step in the generation of the electrical response. Ca^{2+} entering *via* the CNG channel gates a Ca^{2+}-activated Cl^- channel that contributes substantially to the sensory response. Ca^{2+} also binds to calmodulin lowering the ligand sensitivity of the CNG channels. Ca^{2+}-calmodulin also stimulates the activity of a phosphodiesterase reducing the concentration of cAMP. Ca^{2+} is finally extruded by an Na^+/Ca^{2+} exchanger. This cascade of events results in the cell membrane shifting its resting potential from −65 to −45 mV. This depolarization spreads by passive current flow through the dendrite to the soma where it activates voltage-gated Na^+ channels, initiating impulse generation. The combination of Na^+ current with voltage-dependent K^+ currents and with a small

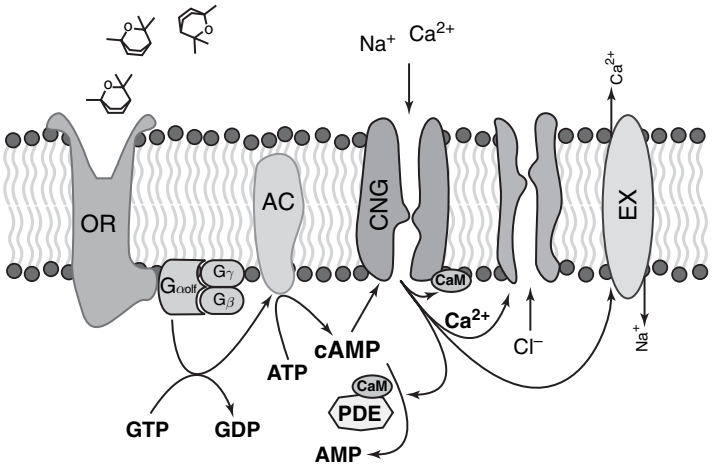

Figure 3 The olfactory transduction cascade. The binding of an odorant molecule (cineole is represented here) to the odorant receptor (OR) leads to the interaction of the receptor to a GTP-binding protein (G_{olf}). This interaction in turn leads to the release of the GTP-coupled alpha subunit of the G protein, which then stimulates the adenylyl cyclase (AC) to produce elevated levels of cAMP. The increase of cAMP opens cyclic nucleotide-gated channels (CNG) causing an odorant-induced inward current carried by Na^+ and Ca^{2+} ions and an alteration of the membrane potential. Ca^{2+} entering *via* the CNG channel gates a Ca^{2+}-activated Cl^- channel that contributes substantially to the sensory response. Ca^{2+} also binds to calmodulin (CaM) lowering the ligand sensitivity of the CNG channels. Ca^{2+}-calmodulin also stimulates the activity of a phosphodiesterase (PDE) reducing the concentration of cAMP. Ca^{2+} is finally extruded by a Na^+/Ca^{2+} exchanger (EX).

Ca^{2+} current acts to produce one or more action potentials that can propagate *via* the axon to the olfactory bulb of the brain.

In OSNs, odors do not only trigger the signaling cascade but also generate various mechanisms to fine-tune the odor-induced current, including a low-selective odor inhibition of the olfactory signal. This wide-range olfactory inhibition is taking place at the level of the CNG channels (Delay, R. and Restrepo, D., 2004; Chen, T. Y. *et al.*, 2006). Interestingly, the inhibitory effect is small in the homomeric CNGA2 channels but larger in channels consisting all olfactory native subunits. The potency of the suppression on the cloned CNG channel appears to be smaller than that previously shown in native olfactory neurons, suggesting that CNG channels switch on and off the olfactory signaling pathway and that the on and off signals may both be amplified by the subsequent olfactory signaling steps.

Nonmotile cilia on OSNs compartmentalize signaling molecules, including odorant receptors and CNG channels, allowing for efficient, spatially confined responses to sensory stimuli. Indeed, CNG channels have been found to have a particular spatial distribution along the ciliary length of OSNs (Flannery, R. J. *et al.*, 2006). The proximal cilia segment, which (in frog) is the first 20% of the cilium, appears to express a small fraction of the CNG channels, whereas the distal segment contains the majority, mostly clustered in one region. Movement of proteins within the cilia is governed by intraflagellar transport, a process that facilitates bidirectional movement along microtubules. Work in *C. elegans* has established that heterotrimeric and homodimeric kinesin-2 family members play a critical role in anterograde transport. Recently, it has been shown that the ciliary targeting of olfactory CNG channels requires the presence of both the CNGB1b channel subunit and the kinesin-2 motor protein, KIF17 (Flannery, R. J. *et al.*, 2006). A critical carboxy-terminal motif (RVxP) on CNGB1b is required for ciliary trafficking of olfactory CNG channels. These results have been further confirmed by the invalidation of the CNGB1 protein leading to olfactory dysfunction and subciliary CNG channel trapping (Michalakis, S. *et al.*, 2006). Indeed, in CNGB1-/- mice, the CNGA2/CNGA4 channels are targeted to the plasma membrane of olfactory knobs but fail to be trafficked into olfactory cilia. Interestingly, a similar trafficking defect can be observed in mice deficient for the CNGA4 subunit. These results demonstrate that CNGB1 has a dual function *in vivo*. First, it gives the olfactory CNG channel a variety of modulatory and biophysical properties tailored to the specific requirements of olfactory transduction. Second, together with the CNGA4 subunit, CNGB1 is needed for ciliary targeting of the olfactory CNG channel.

Olfactory axons are able to elongate and establish synaptic contacts with target neurons in the olfactory bulb throughout adulthood. Axonal pathfinding and target recognition are critical steps in the formation of specific axonal connections in the developing nervous system. These processes could be controlled by local cues, either molecular or structural, that develop in the region of the axon tract. Recently, cyclic nucleotides have been receiving much attention as important regulators in determining whether environmental cues are functioning as attractive or repulsive for growth cone behavior (Song, H. J. *et al.*, 1997; Hopker, V. H. *et al.*, 1999; Song, H. J. and Poo, M. M., 1999). The effects of cyclic nucleotides on growth cone behavior may be partially mediated by CNG channels. CNG channel subunits have been identified in chemosensory neurons in *C. elegans* and shown to be important in the growth and targeting of axons (Coburn, C. M. and Bargmann, C. I., 1996). Active growth cones have been shown to exhibit Ca^{2+} waves which may spread into the neurite (Gu, X. and Spitzer, N. C., 1995; Spitzer, N. C. *et al.*, 1995). These effects are dependent on extracellular calcium, but none of the voltage-gated Ca^{2+} calcium channels expressed in growth cones seem to be involved (Gomez, T. M. *et al.*, 1995; Gottmann, K. and Lux, H. D., 1995). It is possible that CNG channels play an important function in the regulation of Ca^{2+} in the growth cone. Besides the effects of cyclic nucleotides on growth cone behavior, NO has also been shown to significantly affect growth cone behavior. Cheung W. S. *et al.* (2000) showed that NO can stabilize growth cone filopodia, similar to previous findings with 8-Br-cAMP. Van Wagenen S. and Rehder V. (1999) have extended these findings by showing that the response of the growth cone to NO is mediated via a cascade implying cGMP and entry of external Ca^{2+}. These effects of NO on growth cone behavior may also be mediated by CNG channels. Thus, Kafitz K. W. *et al.* (2000) have shown that cyclic nucleotides and NO activate a calcium entry mechanism in olfactory receptor growth cones with properties similar to the CNG channels. Since CNG channels, especially the NO-gated homomeric CNGA4 channels, are highly permeable to Ca^{2+} (Broillet, M.-C. and Firestein, S., 1997) this may

provide a direct mechanism through which NO can regulate calcium levels and behavior of growth cones. In summary, CNG channels present at the membrane of the olfactory growth cones might play a key role in OSNs development and turnover.

4.29.5 Modulation

CNG channels are modulated by cellular factors, including phosphorylation enzymes (Gordon, S. E. *et al.*, 1992; Molokanova, E. *et al.*, 1997; Muller, F. *et al.*, 1998), transition metal divalent cations (Ildefonse, M. *et al.*, 1992; Karpen, J. W. *et al.*, 1993; Gordon, S. E. and Zagotta, W. N., 1995a), lipids such as diacylglycerol (Gordon, S. E. *et al.*, 1995a; Crary, J. I. *et al.*, 2000a; 2000b), endogenous Ca^{2+}-binding proteins (Gordon, S. E. and Zagotta, W. N., 1995b) (Balasubramanian, S. *et al.*, 1996; Rebrik, T. I. and Korenbrot, J. I., 1998) and, in particular, Ca^{2+}-calmodulin (Hsu, Y.-T. and Molday, R. S., 1993; Chen, T.-Y. and Yau, K.-W. 1994; Gordon, S. E. and Zagotta, W. N., 1995b).

When exposed to short repetitive pulses of odors, OSNs rapidly adapt to the stimulus by decreasing their responsiveness in a Ca^{2+}-dependent manner (Kurahashi, T. and Shibuya, T., 1990). Kurahashi T. and Menini A. (1997) have investigated the localization of the principal molecular mechanism for adaptation in the olfactory transduction process and have shown that both the cAMP- and the odor-induced responses have similar adaptation properties, indicating that the entire adaptation process takes place after the production of cAMP and may be mediated by Ca^{2+}-calmodulin-dependent inhibition of the olfactory CNG channel. Experiments on olfactory adaptation performed in knockout mice of the CNGA4 subunit have confirmed that the molecular mechanism for adaptation is localized at the channel level, most likely through CNG channel inhibition by Ca^{2+}-calmodulin (Munger, S. D. *et al.*, 2001). Moreover, comparing properties of native channels with heterologously expressed heteromeric channels, the modulatory subunits CNGA4 and CNGB1b have been shown to be responsible for the physiological modulation of the olfactory CNG channel by Ca^{2+}-calmodulin. Bradley J. *et al.* (2001a; 2001b; 2004) and Munger S. D. *et al.* (2001) measured, in excised patches containing native heteromeric olfactory CNG channels, a fast current inhibition upon addition of Ca^{2+}-calmodulin that persisted for several seconds also after calmodulin was removed in Ca^{2+}-free solution. CNGA4 indeed has calmodulin binding sites. CNGA4 has a IQ-type calmodulin binding site located at the C-terminal region, while CNGB1b has a similar IQ-type site located at the N-terminal region and a basic amphiphilic α-helix (Baa) motif in the C-terminal region. It has been shown that the IQ-type sites are necessary and sufficient for Ca^{2+}-calmodulin channel inhibition, whereas the Baa-type site is not necessary (Bradley, J. *et al.*, 2004; 2005). However, the molecular mechanism by which the binding of Ca^{2+}-calmodulin decreases the ligand sensitivity of the olfactory channel is not yet understood.

Multiple studies of native CNG channels have shown that the addition of micromolar concentrations of intracellular Ca^{2+} is able to decrease the channel sensitivity to cGMP or cAMP, probably by activating a Ca^{2+}-responsive endogenous factor already pre-associated with the channel (Kramer, R. H. and Siegelbaum, S. A., 1992; Lynch, J. W. and Lindemann, B., 1994; Gordon, S. E. *et al.*, 1995b; Balasubramanian, S. *et al.*, 1996; Rebrik, T. I. and Korenbrot, J. I. 1998; Kleene, S. J., 1999; Bradley, J. *et al.*, 2004). Bradley J. *et al.* (2004) have shown that Ca^{2+}-free calmodulin, called apocalmodulin, is able to bind to the heterologously expressed heteromeric olfactory CNG channels even in the absence of Ca^{2+}. Moreover, when Ca^{2+} concentration rises above 100 nM, Ca^{2+} can rapidly modulate the CNG channel sensitivity by directly binding to the pre-associated calmodulin. Furthermore, it has been suggested (Bradley, J. *et al.*, 2004) that, in native channels also, the pre-associated endogenous factor can be apocalmodulin, although a demonstration is still missing. Since Ca^{2+} enters into the olfactory cilia through the CNG channel itself, the pre-associated Ca^{2+}-responsive factor can provide a very fast feedback modulation at the channel level. It has been further verified that the CNGA4 channel subunit plays a central role in Ca^{2+}-calmodulin-dependent odor adaptation (Bradley, J. *et al.*, 2001b; Kelliher, K. R. *et al.*, 2003). Recently, phosphatidylinositol-3,4,5-trisphosphate (PIP3) has been shown to inhibit the activation of the olfactory CNG channels binding to the amino-terminal region of the channel occluding the action of Ca^{2+}-calmodulin (Brady, J. D. *et al.*, 2006).

In addition to their activation by cyclic nucleotides, NO-generating compounds can directly open the olfactory CNG channels through a redox reaction that results in the S-nitrosylation of a free SH group on a cysteine residue (Broillet, M.-C. and

Firestein, S., 1996). This posttranslational modification, comparable to phosphorylation, can modulate the activity of different proteins such as the NMDA receptor, caspases, and others. The NO target site on the CNG channel has been identified by mutating the four candidate intracellular cysteine residues Cys-460, Cys-484, Cys-520, and Cys-552 of the rat CNGA2 subunit into serine residues. All mutant channels continue to be activated by cyclic nucleotides, but only one of them, the C460S mutant channel, exhibits a total loss of NO sensitivity (Broillet, M.-C., 2000). This result is further supported by a similar lack of NO sensitivity that is found for a natural mutant of this precise cysteine residue, the *D. melanogaster* CNG channel. Cys-460 is located in the C-linker region of the channel known to be important in channel gating. Kinetic analyses suggest that at least two of these Cys-460 residues on different channel subunits are involved in the activation by NO. These results show that one single cysteine residue is responsible for NO sensitivity but that several channel subunits need to be activated for channel opening by NO. The corresponding cysteine on the CNGA4 subunit is the cysteine 352. This subunit cannot form homomeric channels that can be activated by cyclic nucleotides, but they can be activated by NO. The properties of these NO-gated channels reveal striking differences with those of either the native rat olfactory CNG channels or the homomeric CNGA2 channels such as the presence of open channel noise and a very different calcium permeability (Broillet, M.-C. and Firestein, S., 1997). These homomeric CNGA4 channels may be expressed at different cellular locations such as the immature olfactory neurons or the vomeronasal neurons and fulfill different physiological roles than the heteromeric CNG channels.

Recently, patch-clamp experiments have revealed that many OSNs respond not only to odors, but also to mechanical stimuli delivered by pressure ejections of odor-free Ringer solution (Grosmaitre, X. *et al.*, 2007). The mechanical responses correlate directly with the pressure intensity and show several properties similar to those induced by odors, including onset latency, reversal potential and adaptation to repeated stimulation. Blocking adenylyl cyclase III or knocking out the CNGA2 subunit eliminates both the odor and the mechanical responses, suggesting that both are mediated by a shared cAMP/CNG channel cascade. This mechanosensitivity enhances the firing frequency of individual neurons when they are weakly stimulated by odors and most likely drives the rhythmic activity (theta oscillation) in the olfactory bulb to synchronize with respiration.

4.29.6 Pharmacology

Although there is a formidable array of specific blockers for sodium, calcium, and potassium channels, specific blockers for CNG channels are scarce. A number of pharmacological agents including L-*cis*-diltiazem (Haynes, L. W., 1992), tetracaine (Fodor, A. A. *et al.*, 1997), pimozide (Nicol, G. D., 1993), and LY-58558 (Leinders-Zufall, T. and Zufall, F., 1995) have been reported to block the current through CNG channels, but these agents have significant drawbacks. First, they exert their effect on the cytoplasmic face of the channel, making their utility questionable in more intact preparations. Second, these blockers have multiple targets, making results difficult to interpret. Recently, Brown R. L. *et al.* (1999) have found a peptide toxin purified from the venom of the Australian King Brown snake, which they have named pseudechetoxin (PsTx). When applied to the extracellular face of membrane patches containing rat CNGA2 channels, PsTx blocks the cGMP-dependent current with a K_i of 5 nM. The block is independent of voltage and requires only a single molecule of toxin. PsTx also blocks CNG channels composed of bovine CNGA1 subunits with high affinity (100 nM), but it is less effective on the heteromeric version of the rod channel (K_i approximately 3 μM). PsTs acts as a pore blocker occluding the entrance to the channel by forming high-affinity contacts with the pore turret (Brown, R. L. *et al.*, 1999). This toxin is structurally classified as a cysteine-rich secretory protein and exhibits structural features that are quite distinct from those of other known small peptidic channel blockers (Yamazaki, Y. *et al.*, 2002). It has now been crystallized and analyzed using X-ray diffraction. PsTx could to be a valuable pharmacological tool for studies on the structure and physiology of CNG channels.

4.29.7 Conclusion

The activation of CNG channels is a complex process comprising the initial ligand binding and a consecutive allosteric transition from a closed to an open configuration. The recent studies on CNG channels have demonstrated the importance of different regions of the protein in activation and modulation of this class of ion channels.

The direct activation by cyclic nucleotides is not only controlled at the CN-binding site where cyclic nucleotide recognition and channel activation take place but particular amino acid residues located elsewhere on the protein also modulate the affinity and efficacy of cAMP or cGMP. Allosteric changes in the CN-binding site, movement of certain regions of the channel molecule, like the C-linker region, seem to be of fundamental importance in the control of the gating mechanisms of the channel. The pore region is responsible for ionic selectivity and for the control of physiological Ca^{2+} permeation, whereas the amino-terminal and the carboxy-terminal regions of the channel take part in channel modulation.

CNG channels first identified in rods and olfactory receptors are now distributed throughout the different cells of the body and may have important roles such as cell motility, secretion, development, and neural plasticity. Indeed, CNG channels have been found in the central nervous system (Kingston, P. A. *et al.*, 1996; Bradley, J. *et al.*, 1997; Wei, J. Y. *et al.*, 1998) and have been implicated in processes as diverse as synaptic modulation, central communication, plasticity, and axon outgrowth in animals ranging from the nematode to mammals (Coburn, C. M. and Bargmann, C. I., 1996; Zufall, F. *et al.*, 1997). CNG channel subunits, in particular the olfactory CNG channel subunits have been identified in the brain (Bradley, J. *et al.*, 1997; Kingston, P. A. *et al.*, 1999; Podda, M. V. *et al.*, 2005; Tetreault, M. L. *et al.*, 2006). Specific subsets of neurons such as the CA1 and CA3 neurons of the hippocampus express CNG channel subunits (Kuzmiski, J. B. and MacVicar, B. A., 2001) suggesting that these channels have a particular function in the central nervous system that is related specifically to certain cell types, rather than being of a general housekeeping nature (Zufall, F. *et al.*, 1997; Wei, J. Y. *et al.*, 1998). Ca^{2+} imaging studies have found that a rise in intracellular Ca^{2+} in hippocampal neurons could result from elevated intracellular cyclic nucleotide concentrations, suggesting that CNG channels play a role in the synaptic plasticity underlying learning and memory (Leinders-Zufall, T. *et al.*, 1995; Bradley, J. *et al.*, 1997; Kingston, P. A. *et al.*, 1999). Indeed, long-term potentiation is attenuated in mutant mice lacking CNGA2 (Parent, A. *et al.*, 1998).

A CNG channel, similar to the olfactory CNGA2, is also expressed throughout the heart of the mouse, but its function remains unclear (Ruiz, M. L. *et al.*, 1996). As sensors of cyclic nucleotide concentrations and conduits for Ca^{2+} entry, CNG channels may play a role in regulating the heart rate and contraction. The cloning and first functional characterization of a plant CNG channel occurred from the *Arabidopsis* cDNA (Leng, Q. *et al.*, 1999). This channel could, like its animal counterparts, translate stimulus-induced changes in cytosolic cyclic nucleotides into altered cell membrane potential and/or cation flux as part of signal cascade pathway(s) that remain to be identified. Future work will reveal new functions for CNG channels as well as more information about their structure–functions and modulation.

4.30.1 Introduction

Titus Lucretius Carus, a Roman poet and philosopher, proposed in his book *On the Nature of Things* (50 BC) that a variety of odors exist because each odorant possesses a unique structure (Lucretius, T., 1995). In the mid-twentieth century, this concept was established as the stereospecific receptor theory, which provides an explanation for the molecular mechanisms underlying the remarkable olfactory sensing system (Amoore, J. E., 1963). The receptor theory postulates that there are receptor sites for odorants and that odor perception occurs only when the structure of an odorant molecule and the binding site match. Other theories including vibrational theory, puncturing theory, radiational theory, and absorption theory have been proposed to explain odor perception, but they remain unproven.

Based on the evidence for the involvement of G protein-mediated signaling and ion channels in olfactory signal transduction (Pace, U. *et al.*, 1985; Sklar, P. B. *et al.*, 1986; Nakamura, T. and Gold, G. H., 1987; Breer, H. *et al.*, 1990; Dhallan, R. S. *et al.*, 1990), Buck and Axel hypothesized that receptor proteins for odorants must be expressed in the olfactory epithelium and must belong to a family of seven-transmembrane G-protein-coupled receptors (GPCRs) (Buck, L. B., 2004). State-of-the-art molecular biology techniques allowed them to identify a multigene family that appears to encode receptors for odorants (Buck, L. and Axel, R., 1991). The proteins were named olfactory or odorant receptors (ORs). The former name was given because the proteins are expressed in olfactory neurons and play a crucial role in olfaction, and the latter because the proteins bind odorant molecules; however, strictly saying, neither terminology is correct because ORs

have since been found in tissues other than the olfactory epithelium and because ORs have functions in addition to acting as odorant sensors (Spehr, M. *et al.*, 2006a). Nonetheless, the main role of the OR family is to provide a molecular basis for recognition and discrimination of thousands of odorant molecules in the olfactory sensory system.

4.30.2 Structure

4.30.2.1 Protein Structure

OR proteins are classified as members of the GPCR superfamily because of the presence of structural features common to GPCRs (Buck, L. and Axel, R., 1991; Strader, C. D. *et al.*, 1994) and because they couple to and activate heterotrimeric G proteins (Krautwurst, D. *et al.*, 1998; Kajiya, K. *et al.*, 2001). ORs possess seven hydrophobic transmembrane domains, a disulfide bond between the conserved cysteines in the extracellular loops, a conserved glycosylation site in the N-terminal region (Katada, S. *et al.*, 2004), and several amino acid sequences that are conserved in the OR family (Zozulya, S. *et al.*, 2001; Zhang, X. and Firestein, S., 2002) (Figure 1). The OR consensus sequences reside within the cytoplasmic side of each transmembrane regions and include PMYFFL (transmembrane domain [TM]2), MAYDRYVAIC (TM3), KAFSTC (TM6), and PMLNPXXY (TM7). Although these consensus sequences vary somewhat between species, they have been widely used to retrieve OR genes from genome. In addition, extensive motif analysis has revealed more than 80 specific short motifs, some of which constitute signature sequences for the OR subfamily of a certain species or have implications for the function and evolution the ORs (Liu, A. H. *et al.*, 2003). These conserved motifs likely contribute to the proper folding of ORs in the plasma membrane so that ORs can bind odorants and couple to appropriate G proteins. The transmembrane regions, on the other hand, help form the odorant-binding pocket (Figure 1). The sequences in the binding pocket are relatively variable, allowing ORs to bind a wide spectrum of odorant molecules (Singer, M. S. *et al.*, 1996; Pilpel, Y. and Lancet, D., 1999; Floriano, W. B. *et al.*, 2000; Singer, M. S., 2000; Floriano, W. B. *et al.*, 2004; Man, O. *et al.*, 2004; Katada, S. *et al.*, 2005). Overall, the three-dimensional structure of the OR is probably similar to that of rhodopsin, which has been determined by a combination of computer modeling, site-directed mutation, and

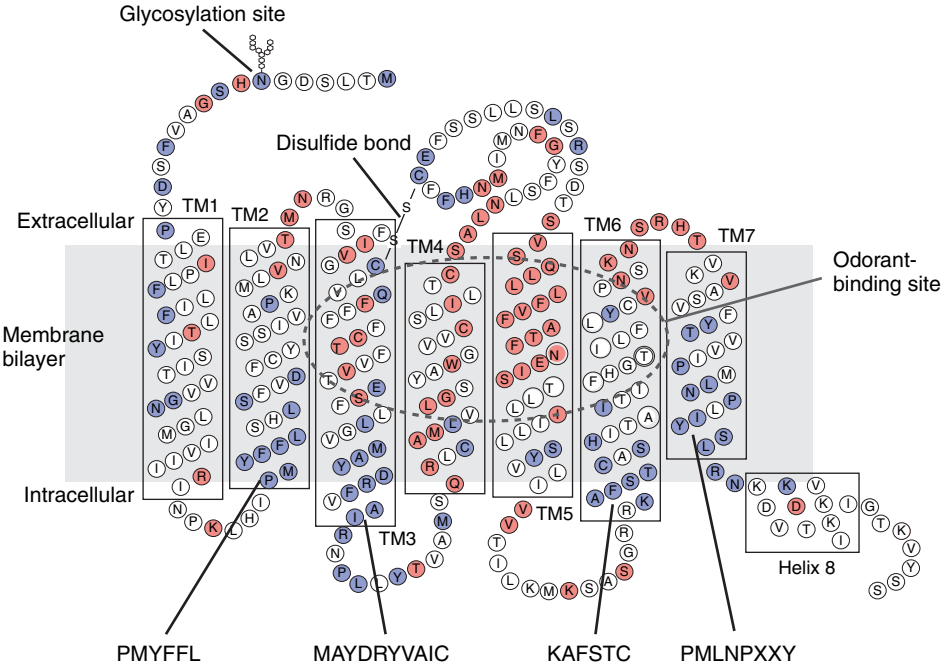

Figure 1 Structure and topology of an olfactory receptor (OR) protein. Conserved sequence motifs, glycosylation site, and disulfide bond in the OR family are shown. The odorant-binding site is in the space formed by TM3-6 (dotted circle). Red, variable amino acids in the OR family; blue, conserved amino acids in the OR family. TM, transmembrane domain.

X-ray crystallography and which is the only GPCR structure that has been solved so far (see Odorant-Binding Site) (Katada, S. *et al.*, 2005).

4.30.2.2 Olfactory Receptor Genes

It has been estimated that the OR family includes at least several hundred members in the rat (Buck, L. and Axel, R., 1991). In the last decade or so, the genome sequence projects have enabled the comprehensive analysis of the OR gene family and have revealed the genomic structure and distribution of the OR genes from various organisms (Mombaerts, P., 2004). The most recent data for vertebrate ORs are shown in Table 1. In mammals, the OR repertoire comprises 800–1500 members, whereas in fish, the OR family has only approximately 100 members (Niimura, Y. and Nei, M., 2005c). Thus, expansion of the OR gene family occurred when animals shifted their living space from an aquatic to a terrestrial environment.

Based on phylogenetic analysis, the mammalian OR genes can be classified into two different groups: class I and class II (Glusman, G. *et al.*, 2001; Zozulya, S. *et al.*, 2001; Zhang, X. and Firestein, S., 2002) (Figure 2). This classification is based on the finding that frog (*Xenopus laevis*) has two different classes of OR genes: one (class I) that is similar to fish OR genes and a second (class II) that is similar to mammalian OR genes (Freitag, J. *et al.*, 1995). For example, the numbers of intact class I OR genes in human and mouse are 57 and 115 of 388 and 1037 total intact OR genes, respectively (Niimura, Y. and Nei, M., 2005c). Later studies revealed, however, that mammalian class I genes formed a distinct clade from fish OR genes that can be further divided into nine subgroups (Niimura, Y. and Nei, M., 2005c) (Figure 2). The amphibian OR repertoire turns out to be similar to both fish and mammal ORs,

Table 1 Functional and nonfunctional OR genes in various vertebrate species

	Organism	*Total genes*	*Intact genes*	*Pseudogene* (%)	*Reference*[a]
Mammal	Human	802	388	52	Niimura Y. and Nei M. (2005a; 2005b; 2005c)
	Mouse	1391	1037	25	Niimura Y. and Nei M. (2005a; 2005b; 2005c)
	Rat	1493	1202	20	Quignon P. *et al.* (2005)
	Dog	1094	872	20	Quignon P. *et al.* (2005)
Bird	Chicken[b]	554	78	86	Niimura Y. and Nei M. (2005a; 2005b; 2005c)
Amphibian	*X. tropicalis*	888	410	54	Niimura Y. and Nei M. (2005a; 2005b; 2005c)
Fish	Zebrafish	133	98	26	Niimura Y. and Nei M. (2005a; 2005b; 2005c)
	Puffer fish	94	40	57	Niimura Y. and Nei M. (2005a; 2005b; 2005c)

[a]Note that there have been many reports on the estimates of the numbers of olfactory receptor (OR) genes, but the most recent ones are shown here. The numbers will be subject to change slightly with time in the future.
[b]The actual number of chicken ORs appears to be much larger due to numerous short contings in the draft genome.

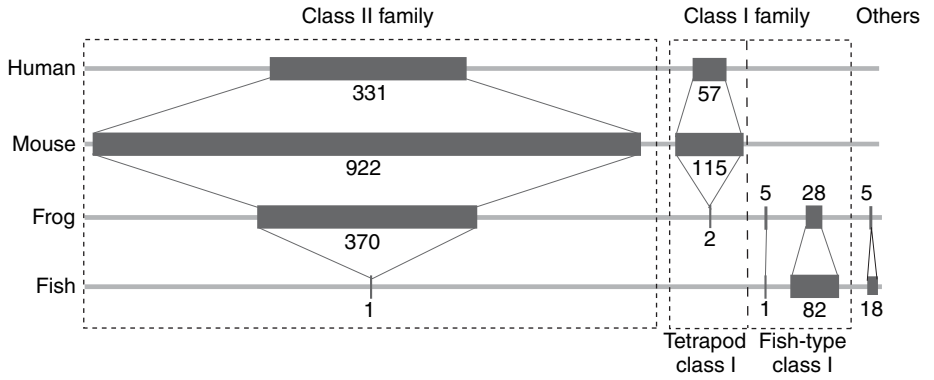

Figure 2 Numbers of functional olfactory receptor (OR) genes belonging to different groups in four species. The class II family has originated from one ancestral gene in fish. The class I family can be divided into two classes; tetrapod class I and fish-type class I.

suggesting that there are at least three evolutional lineages (i.e., fish, amphibian, and mammal) in the vertebrate OR gene family (Niimura, Y. and Nei, M., 2005c).

Relatively few OR genes have been found in insects. For example, there are 62 OR genes expressed in the antenna and the maxillary palps in *Drosophila melanogaster* (Clyne, P. J. *et al.*, 1999; Gao, Q. and Chess, A., 1999; Vosshall, L. B. *et al.*, 1999). Similar numbers of OR genes have been found in the genome of the malaria mosquito (Fox, A. N. *et al.*, 2002; Hill, C. A. *et al.*, 2002) and from several moths (Krieger, J. *et al.*, 2002; 2003; Nakagawa, T. *et al.*, 2005). The insect ORs have the following unique features: (1) they lack obvious homology with vertebrate ORs or other GPCRs (Robertson, H. M. *et al.*, 2003); (2) there do not appear to be pseudogenes (Robertson, H. M. *et al.*, 2003); (3) they are coexpressed and heterodimerize with the unique OR, which is highly conserved across diverse insect species, also known as the Or83b family (Larsson, M. C. *et al.*, 2004; Nakagawa, T. *et al.*, 2005; Neuhaus, E. M. *et al.*, 2005); and (4) their membrane topology is distinct from conventional GPCRs so that their N-termini are located intracellularly (Benton, R. *et al.*, 2006).

4.30.2.3 Olfactory Receptor Pseudogenes

A significant portion of the OR gene family has been pseudogenized in vertebrates. Hominoids possess a high pseudogene content (~50%), whereas only ~20% of OR genes are pseudogenes in mouse and dog and 25–35% are pseudogenes in primates (Gilad, Y. *et al.*, 2004; Niimura, Y. and Nei, Y., 2005c; Quignon, P. *et al.*, 2005) (Table 1). The ORs are the most changeable gene family and still undergo rapid molecular evolution by tandem gene duplication and pseudogenization in the lineage of each animal species. For example, the mouse lineage acquired a few hundred new OR genes after the human–mouse divergence, indicating that both gene expansion in the mouse lineage and gene loss in the human lineage contribute to the differences in the numbers of functional ORs (Niimura, Y. and Nei, M., 2005b). The OR gene dynamics could also be pressured by the state of the environment and the type of sense that is utilized for social and sexual behavior. The fraction of pseudogenes in the OR family has increased during evolution in the order of rodents, monkeys, and humans, suggesting that the reduced sense of smell correlates with the loss of functional OR genes. Indeed, in whale and dolphin, in which the auditory system is dominant, 70–80% of OR genes appear to be pseudogenes (Y. Go, personal communication).

4.30.2.4 Genomic Structure

The OR genes are encoded by an exon that contains an intronless coding region of ~1 kb along with one to four upstream exons (Lane, R. P. *et al.*, 2001; Young, J. M. and Trask, B. J., 2002). The OR genes form genomic clusters and are distributed widely in chromosomes; however, the distribution is not even, and almost half of the mouse OR genes are located on chromosomes 2 and 7, which have orthologous relationships with chromosome 11 in human (Niimura, Y. and Nei, M., 2005a). The majority of the OR gene family has multiple transcriptional isoforms (Asai, H. *et al.*, 1996; Lane, R. P. *et al.*, 2001; Volz, A. *et al.*, 2003; Fukuda, N. and Touhara, K., 2006). Further, OR genes are highly polymorphic as suggested for human leukocyte antigen-linked OR genes (Ehlers, A. *et al.*, 2000; Eklund, A. C. *et al.*, 2000) and dog OR genes (Tacher, S. *et al.*, 2005), which may account for individual differences in the ability to perceive odor and may sometimes cause specific anosmia.

4.30.3 Expression

4.30.3.1 Single-Receptor Gene Choice

Each olfactory sensory neuron expresses just one of the 1000 ORs (Serizawa, S. *et al.*, 2004; Shykind, B. M., 2005). The one-neuron one-receptor rule has been confirmed by a variety of techniques, namely, *in situ* hybridization (Ngai, J. *et al.*, 1993; Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993), single-cell reverse transcriptase-polymerase chanin reaction (RT-PCR) analysis (Malnic, B. *et al.*, 1999; Touhara, K. *et al.*, 1999), and transgenic experiments (Qasba, P. and Reed, R. R., 1998; Serizawa, S. *et al.*, 2000; Vassalli, A. *et al.*, 2002; Serizawa, S. *et al.*, 2003). Further, the selected OR appears to be transcribed from only one of two alleles, either the maternal or paternal allele (Chess, A. *et al.*, 1994; Ishii, T. *et al.*, 2001). This mutually exclusive expression pattern is preserved even between transgenes and endogenous copies, supporting the stochastic model (Qasba, P. and Reed, R. R., 1998; Serizawa, S. *et al.*, 2000; Vassalli, A. *et al.*, 2002; Serizawa, S. *et al.*, 2003). Indeed, the single OR choice is observed from a minigene that contains

a few kilobases upstream of the transcription start site, implicating the involvement of cis-regulatory elements (Qasba, P. and Reed, R. R., 1998; Vassalli, A. *et al.*, 2002; Oka, Y. *et al.*, 2006).

The expression of one cluster of OR genes including MOR28 in transgenic mice requires a long upstream region of ~100 kb containing an enhancer element called the H-region (Serizawa, S. *et al.*, 2000; 2003). This locus control region, H, appears to associate with multiple OR promoters and act as a cis-acting enhancer element (Lomvardas, S. *et al.*, 2006) (Figure 3). In olfactory neurons, one of the two H-region alleles is methylated, suggesting that the H-enhancer is functionally monoallelic, therefore ensuring selection of a single receptor (Lomvardas, S. *et al.*, 2006).

In addition to positive regulation of OR gene expression by cis-regulatory elements, negative feedback regulation must occur to suppress the expression of additional receptors (Serizawa, S. *et al.*, 2003; Lewcock, J. W. and Reed, R. R., 2004; Shykind, B. M. *et al.*, 2004). It appears that functional OR proteins but not mRNA play an inhibitory role in preventing further activation of other OR genes, although the molecular mechanism remains to be elucidated (Figure 3).

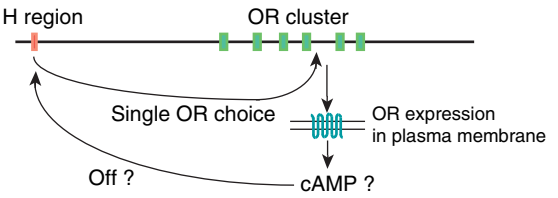

Figure 3 A model for olfactory receptor (OR) gene expression. The H-region containing an enhancer element associates with multiple OR promoters on different chromosomes to activate OR gene expression. The expressed functional OR proteins transmit inhibitory signals to block the action of the H-enhancer, resulting in the expression of only one functional OR in a sensory neuron.

4.30.3.2 Spatial Expression Pattern

In mouse and rat, *in situ* hybridization experiments using different OR probes have suggested that each OR gene is expressed only in a certain region of the olfactory epithelium (Nef, P. *et al.*, 1992; Strotmann, J. *et al.*, 1992; Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993; Strotmann, J. *et al.*, 1994). Thus, the epithelium can be divided into at least four spatial zones expressing different sets of OR genes (Sullivan, S. L. *et al.*, 1996) (Figure 4). The distinct spatial expression pattern appears to be conserved among the vertebrate species, although the expression of fish ORs is not as clearly segregated as that of mammalian ORs (Ngai, J. *et al.*, 1993; Weth, F. *et al.*, 1996). Initially, the

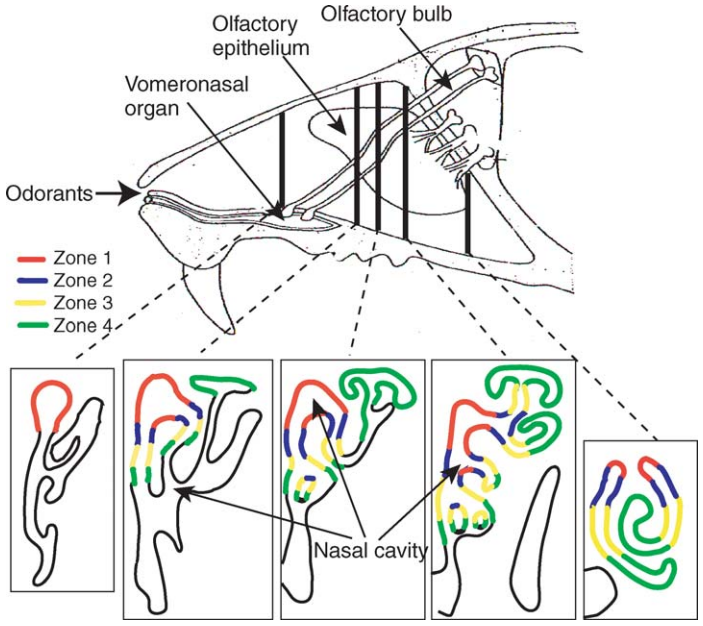

Figure 4 Anatomic structure of nasal cavity and olfactory receptor (OR) expression zones in the olfactory epithelium. The spatial expression zones are depicted in four different colors for clarity, but OR genes are expressed in a unique and distinct zone in a continuous and overlapping manner.

spatial zones observed in rodents were thought to be sharply segregated, but careful *in situ* hybridization studies revealed that each OR gene is expressed in a unique and distinct zone in a continuous and overlapping manner (Norlin, E. M. *et al.*, 2001; Iwema, C. L. *et al.*, 2004; Miyamichi, K. *et al.*, 2005). Therefore, multiple overlapping bands are formed along the dorsomedial/ventrolateral axis, although the boundary of the most dorsal region corresponding to the olfactory cell adhesion molecule (OCAM)-negative neuronal layer was maintained.

There are some exceptions to the zonal expression rule. First, some OR genes are expressed in the septal organ, which is an isolated island of olfactory sensory neurons located on the nasal septum near the entrance of the nasopharynx (Kaluza, J. F. *et al.*, 2004; Tian, H. and Ma, M., 2004). Second, the OR37 subfamily shows a patch-like distribution in clustered populations of neurons in central turbinates (Strotmann, J. *et al.*, 1999). Although there are some promoter motifs that might control the expression domain in the nasal cavity, the regulatory factors that determine the positional information remain to be identified.

4.30.3.3 Temporal Expression Pattern

In rodents, OR genes start to be expressed during the embryonic stages. The onset of expression in mice is at embryonic day (E) 12–14 as determined by *in situ* hybridization for several ORs (Strotmann, J. *et al.*, 1995; Sullivan, S. L. *et al.*, 1995). Microarray analysis of the developmental course of OR gene expression revealed that the number of transcribed OR genes remains at a relatively low level until birth (100–200 ORs), and a large number of OR genes are detectable only after birth (Zhang, X. *et al.*, 2004). At 2–3 weeks after birth, the number of detected OR genes reached a peak (~500 ORs) (Zhang, X. *et al.*, 2004). Recently, specific antibodies against ORs have become available (Barnea, G. *et al.*, 2004; Strotmann, J. *et al.*, 2004), and they have revealed that OR proteins are present in dendritic knobs of olfactory sensory neurons as early as E12 and before the initiation of ciliogenesis (Schwarzenbacher, K. *et al.*, 2005). Because the olfactory cilia are formed at E13, the OR proteins appear to migrate into developing cilia, and strong labeling by the antibody is observed in the expanded tips of the cilia. Up to E18, the number of cilia per neuron continues to increase, during which OR immunostaining is clearly visible.

4.30.3.4 Ectopic Expression

OR expression is not restricted to olfactory sensory neurons. Expression of ORs in nonolfactory tissues was first observed in the male germ line (Parmentier, M. *et al.*, 1992). Since then, ectopic OR transcripts have been found in a variety of tissues including the spleen and insulin-secreting cells (Blache, P. *et al.*, 1998), lingual epithelial cells of the tongue (Durzynski, L. *et al.*, 2005; Gaudin, J. C. *et al.*, 2006), ganglia of the autonomic nervous system (Weber, M. *et al.*, 2002), pyramidal neurons in the cerebral cortex of the brain (Otaki, J. M. *et al.*, 2004), the colon (Yuan, T. T. *et al.*, 2001), myocardial cells in developing heart (Drutel, G. *et al.*, 1995; Ferrand, N. *et al.*, 1999), the prostate gland (Yuan, T. T. *et al.*, 2001), and erythroid cells (Feingold, E. A. *et al.*, 1999). Polyclonal antibodies against an OR expressed in dog sperm bind specifically to the midpiece of the flagellum of mature sperm (Vanderhaeghen, P. *et al.*, 1993; Walensky, L. D. *et al.*, 1995). In other cases, the transcripts have been detected mainly by RT-PCR, and therefore, the expression level might be too low to be considered functional. Indeed, an RNase protection assay and microarray analysis estimated that a total of 50–70 OR genes are expressed in mouse testis (Vanderhaeghen, P. *et al.*, 1997a; 1997b; Zhang, X. *et al.*, 2004), whereas a careful *in situ* hybridization study revealed that only up to 10–20 OR genes were actually detected at a significant level (Fukuda, N. and Touhara, K., 2006) (Figure 5(a)). The testicular ORs are expressed in a subset of the seminiferous

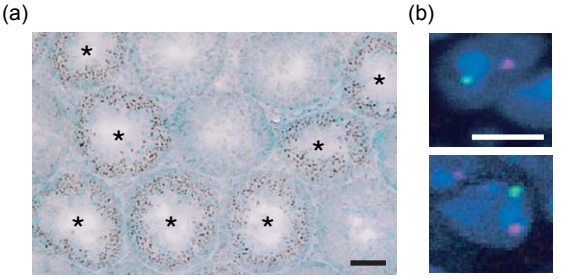

Figure 5 Expression of olfactory receptor (OR) genes in mouse testis. (a) *In situ* hybridization showing expression of an OR in a subset of the seminiferous tubules (asterisks). Scale bar = 0.1 mm. (b) Double-*in situ* hybridization of ORs showing two signals derived from two ORs in nuclei of round spermatids. Scale bar = 10 μm. Adapted from Fukuda, N. and Touhara, K. 2006. Developmental expression patterns of testicular olfactory receptor genes during mouse spermatogenesis. Genes Cells 11, 71–81, with permission from Blackwell Publishing.

tubules, suggesting that they are expressed at specific stages during spermatogenesis (Fukuda, N. and Touhara, K., 2006). Phylogenetic analysis suggests that there is no unique characteristic sequence similarity among the testicular OR genes (Vanderhaeghen, P. *et al.*, 1997b; Zhang, X. *et al.*, 2004; Fukuda, N. and Touhara, K., 2006). Double-*in situ* hybridization experiments showed that, in contrast to olfactory neurons, more than one OR could be expressed in a single spermatogenic cell, indicating that the transcriptional regulation of OR genes in testis is distinct from that in the olfactory system (Fukuda, N. and Touhara, K., 2006) (Figure 5(b)).

4.30.4 Function I: An Odorant Sensor

4.30.4.1 General Considerations for Functional Expression

Understanding of OR function has progressed slowly due to a lack of appropriate heterologous systems for expressing and assaying odorant responses (McClintock, T. S. and Sammeta, N., 2003). Therefore, olfactory neurons themselves were first targeted as an OR expression system (Zhao, H. *et al.*, 1998) because they should possess the appropriate cellular machinery for expressing ORs and transmitting odorant signals. Adenovirus-mediated gene transfer was used to overexpress ectopic ORs in the olfactory epithelium, and the ligand responses were measured either by electro-olfactography (Zhao, H. *et al.*, 1998) or by Ca^{2+} imaging of infected neurons (Touhara, K. *et al.*, 1999) (Figure 6(a)). In addition, a gene-targeting approach was utilized to tag defined OR-expressing olfactory neurons with green fluorescent proteins, after which the responses of the fluorescent cells to the cognate odorants were recorded (Bozza, T. *et al.*, 2002; Grosmaitre, X. *et al.*, 2006). Although this homologous *in vivo* expression system gives reliable odorant responses, high-throughput ligand screening necessitates establishment of heterologous expression systems.

Several attempts have been made to achieve functional expression of ORs on the cell surface in heterologous systems. In some cases, adding an N-terminal leader sequence from another GPCR resulted in a limited expression of functional ORs in the plasma membrane and in a successful odorant response in a heterologous system such as HEK293 cells (Krautwurst, D. *et al.*, 1998; Wetzel, C. H. *et al.*, 1999; Kajiya, K. *et al.*, 2001). Additional studies have shown that glycosylation of the N-terminus of ORs is required for proper translocation to the plasma membrane (Katada, S. *et al.*, 2004). In addition, the one-transmembrane protein RTP1, which has been referred to as an OR chaperone, appears to enhance cell-surface expression of ORs, and many ORs have been deorphanized by coexpressing them with RTP1 (Saito, H. *et al.*, 2004). In addition, Ric8B, a putative guanine nucleotide exchange factor for Gαolf, promotes efficient signal transduction of ORs (Von Dannecker, L. E. *et al.*, 2006). Thus, introduction of all the factors required for OR expression present in olfactory neurons is expected to solve the problems of heterologous expression. In addition, a method for maintaining cell-surface localization is needed because the ORs undergo continuous internalization and recycling in heterologous cells (Jacquier, V. *et al.*, 2006). Thus, the level of surface expression appears

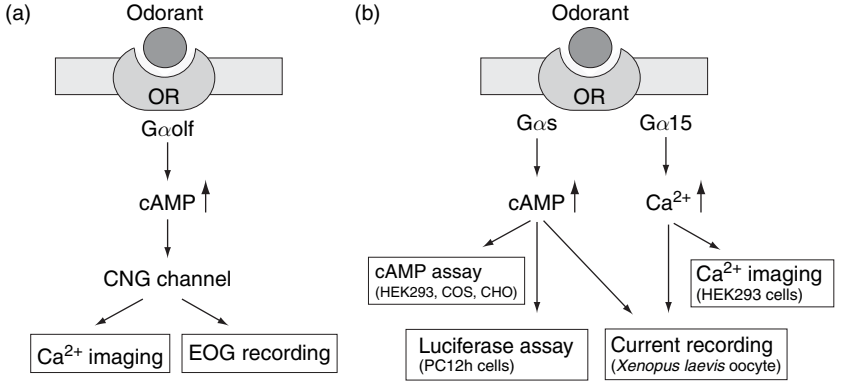

Figure 6 Odorant response assays for an olfactory receptor (OR). (a) Homologous expression of an OR in olfactory neurons. Odorant responses are monitored by Ca^{2+} imaging or electro-olfactogram (EOG). CNG, cyclic nucleotide gated. (b) Heterologous expression of an OR in mammalian cell lines or *Xenopus laevis* oocytes. Odorant responses are measured by Gαs-cAMP or Gα15-Ca^{2+} signaling.

to be critical for OR assays. Finally, it should be noted that there are dramatic differences even between HEK293 cells from different laboratories.

4.30.4.2 Odorant Response Assays

Ca^{2+} imaging has been one of the most common and reliable methods for detecting activation of orphan GPCRs in high-throughput ligand screening. The Ca^{2+} imaging assay, however, is limited to GPCRs that couple to Gαq-type G-proteins. For GPCRs that couple to unknown G proteins, the G-protein α subunit, Gα15, is often used to force the signaling to an inositol phosphate-mediated cascade because of its promiscuity for GPCRs. This strategy has been successfully applied to ORs that couple to the olfactory Gαs-type G-protein, Gαolf, which mediates increases in cAMP in olfactory neurons. Thus, in HEK293 cells coexpressing Gα15 and ORs, Ca^{2+} responses are observed when the cells are stimulated with their ligands (Krautwurst, D. *et al.*, 1998; Kajiya, K. *et al.*, 2001; Touhara, K. *et al.*, 2006) (Figures 6(b) and 7).

Without coexpression of Gα15, ORs activate endogenous Gαs upon ligand stimulation in various mammalian cell lines (e.g., HEK293, COS-7, and CHO-K1 cells) (Kajiya, K. *et al.*, 2001; Katada, S. *et al.*, 2003). Odorant-induced cAMP increases have been measured using an enzyme-linked immunoassay (Touhara, K. *et al.*, 2006) (Figure 6(b)). Alternatively, a luciferase-reporter assay system using the zif268 promoter allows luminescent detection of cAMP increases upon stimulation with an odorant (Katada, S. *et al.*, 2003). For example, in PC12h cells cotransfected with an OR and the luciferase-reporter construct, odorant stimulation produces dose-dependent increases in luciferase activity (Katada, S. *et al.*, 2003).

The *X. laevis* oocyte is another good heterologous expression system for ORs (Figure 6(b)). Ca^{2+} increases via an endogenous Ca^{2+}-dependent Cl^- channel can be electrophysiologically detected by coexpressing Gα15, and Gαs-mediated cAMP increases can be detected by coexpressing a cAMP-dependent Cl^- channel, CFTR (Katada, S. *et al.*, 2003; Abaffy, T. *et al.*, 2006; Touhara, K. *et al.*, 2006). The whole-cell voltage-clamp method allows for measurement of whole-cell ion currents flowing through the membrane via these ion channels. The current induced by an odorant stimulus can be further amplified by measuring the conductance at +60 mV with depolarization step pulses (Touhara, K. *et al.*, 2006).

To elucidate the structural features of an OR at the atomic level, it is necessary to develop a system for overexpressing and crystallizing the OR. This is a problem not only for ORs but also other GPCRs because of the difficulty in handling seven-transmembrane proteins. In this regard, yeast has been proposed as a good overexpression system for future structural analyses of ORs (Pajot-Augy, E. *et al.*, 2003).

4.30.4.3 Olfactory Receptor Pharmacology

The best characterized OR is a mouse OR, mOR-EG (MOR174-9), which was originally isolated from a single eugenol-responsive neuron by Ca^{2+} imaging

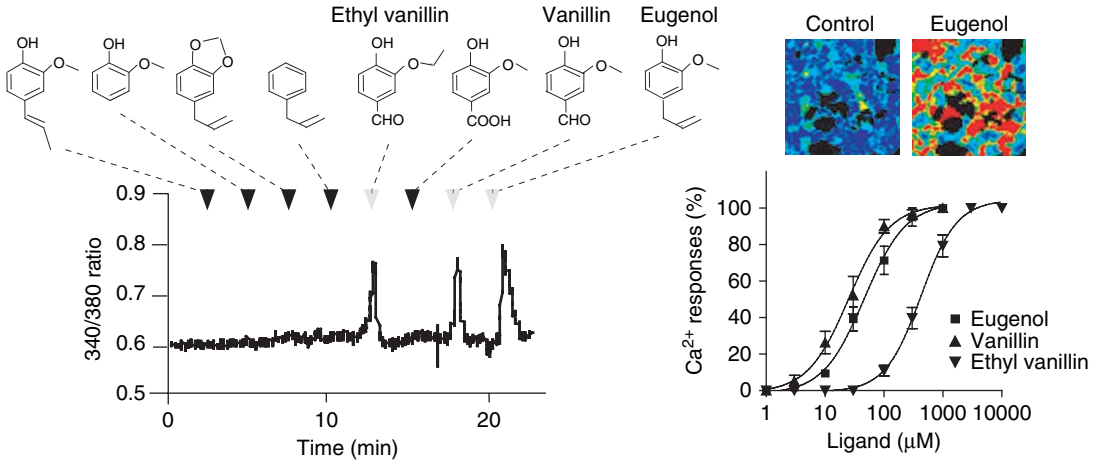

Figure 7 Ca^{2+} responses and dose–response profiles for various ligands in HEK293 cells expressing mOR-EG and Gα15. mOR-EG responds to eugenol, vanillin, and ethyl vanillin with different EC_{50} values. Red cells indicate high levels of intracellular Ca^{2+} and blue cells represent the basal levels in pseudocolored images.

and single-cell RT-PCR techniques (Kajiya, K. *et al.*, 2001). The mOR-EG recognizes 22 odorants that share certain molecular determinants, with EC_{50} values ranging from a few to several hundred micromolar (Katada, S. *et al.*, 2005) (Figures 7 and 8). The structure–activity relationship studies for mOR-EG suggested that ORs have a broad but selective molecular receptive range, and the selectivity is determined by shape, size, functional group, and length of a ligand. This pharmacological concept is generally common to many ORs as has been shown by studies on rat I7 (Araneda, R. C. *et al.*, 2000) and other deorphanized ORs (Wetzel, C. H. *et al.*, 1999; Bozza, T. *et al.*, 2002; Gaillard, I. *et al.*, 2002; Levasseur, G. *et al.*, 2003; Spehr, M. *et al.*, 2003; Matarazzo, V. *et al.*, 2005; Shirokova, E. *et al.*, 2005); however, there seem to be some ORs whose ligand spectra are relatively narrow. The ligand specificity appears to be determined by the environment of the binding site in each OR. Considering that there are a thousand ORs, each of which has a unique ligand spectrum, and that each odorant is recognized by multiple ORs, it is reasonable to conclude that odorant information is coded by a combination of ORs activated by the odorant (Malnic, B. *et al.*, 1999; Kajiya, K. *et al.*, 2001; Touhara, K., 2002) (Figure 9).

As is the case of ligands for other GPCRs, odorants function not only as agonists for some ORs but also as antagonists for others, suggesting that the interaction between ORs and odorants in the mixture can be more complex than expected (Figure 10). For example, the eugenol response to mOR-EG was potently blocked by some structurally related odorants such as methyl isoeugenol and isosafrol (Oka, Y. *et al.*, 2004a; 2004b). The antagonism was observed in mOR-EG-expressing olfactory neurons using an intact olfactory epithelium slice (Omura, M. *et al.*, 2003; Oka, Y. *et al.*, 2004b). Furthermore, rat I7 has been shown to be antagonized by citral (Araneda, R. C. *et al.*, 2000), and undecanal was found to be an inhibitor of hOR17-4 (Spehr, M. *et al.*, 2003). Thus, the antagonism between odorants may contribute significantly to the formation of the receptor code for an odorant mixture in the olfactory system. In reality, however, this type of interaction may be rare because few odorants act as antagonists. Indeed, optical recording in the olfactory bulb shows that a receptor code for a natural odor such as coffee or cumin is basically the sum of the responses to its individual components (Lin da, Y. *et al.*, 2006). Quantitative recording using a Ca^{2+} imaging technique, however, demonstrated that a partial inhibition of the response by antagonists occurs in the OR-defined glomerulus, which may contribute to a change in odor perception (Y. Oka and K. Touhara, unpublished observation).

4.30.4.4 Odorant-Binding Site

Multiple alignment analysis of the OR superfamily identified highly conserved and variable regions that are probably involved in structural organization and in ligand recognition, respectively (Buck, L. and Axel, R., 1991; Zhang, X. and Firestein, S., 2002). Some of the earlier attempts such as correlated mutation analysis (Singer, M. S. *et al.*, 1996) and Fourier analysis of multiple OR sequences (Pilpel, Y. and Lancet, D., 1999; Man, O. *et al.*, 2004) further supported the hypothesis that variable residues are responsible for odorant binding. Alternatively, when cognate ligands for ORs are known, odorant-sensing residues have been predicted using a combination of computer modeling and docking simulation. A total of 10–20 residues in TM3, 4, 5, and 6 are predicted to be involved in ligand recognition and responsible for odorant specificity of ORs based on the coordinates of bacteriorhodopsin, a non-GPCR seven-transmembrane helix protein (Singer, M. S. and Shepherd, G. M., 1994), a later rhodopsin X-ray structure (Floriano, W. B. *et al.*, 2000; Singer, M. S., 2000), a recent computationally determined three-dimensional structure predicted using only the primary sequence (Vaidehi, N. *et al.*, 2002; Floriano, W. B. *et al.*, 2004; Hall, S. E. *et al.*, 2004; Hummel, P. *et al.*, 2005), and computer modeling and calculation of the lowest ligand-binding energy for several ORs.

A systematic experimental approach to identify the odorant-binding site was taken for mOR-EG (Katada, S. *et al.*, 2005). To define the odorant-binding environment, functional analysis was carried out on a series of site-directed mutants along with parallel ligand docking simulations. Most of the critical residues involved in odorant recognition, and therefore sensitive to mutation, were hydrophobic, and the binding pocket was formed by TM3, TM5, and TM6 (Katada, S. *et al.*, 2005) (Figure 11). The spatial location of the binding pocket is similar to that for other biogenic GPCRs, but unlike other GPCRs, which tend to form multiple electrostatic interactions with their ligands, hydrophobic amino acids appear to play critical roles in odorant recognition by ORs. The accuracy of the binding model was confirmed by

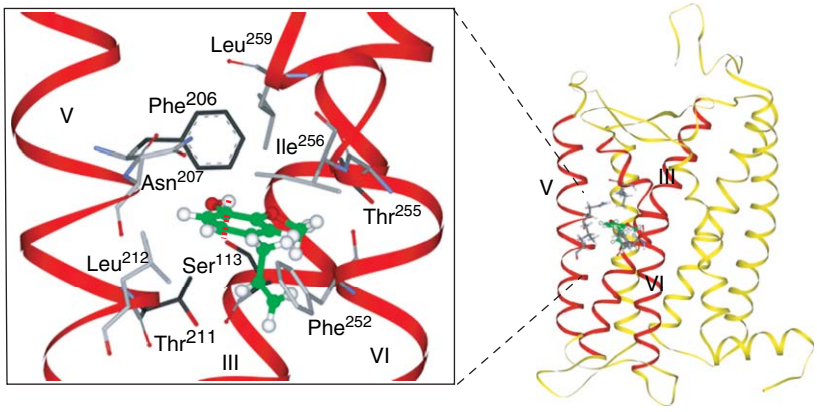

Figure 11 A model for binding of eugenol to mOR-EG and the orientation of amino acids in the binding site. Eugenol is shown in green, and TMIII, V, and VI are shown as red ribbons. Adapted from Katada, S., Hirokawa, T., Oka, Y., Suwa, M., and Touhara, K. 2005. Structural basis for a broad but selective ligand spectrum of a mouse olfactory receptor: mapping the odorant-binding site. J. Neurosci. 25, 1806–1815, Copyright 2005 by the Society of Neuroscience, with permission.

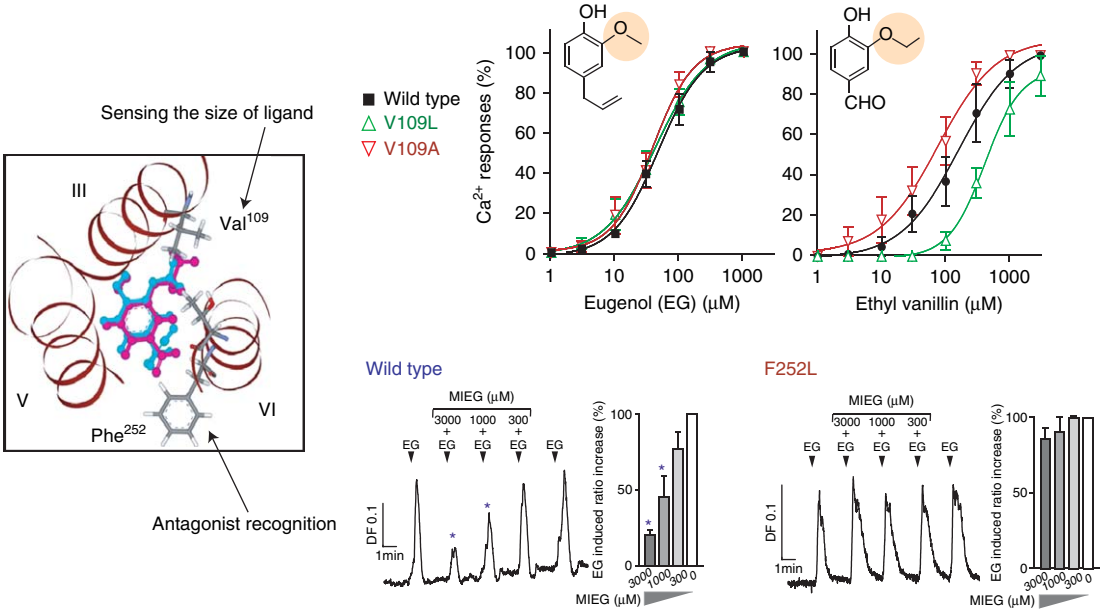

Figure 12 Roles of Val109 and Phe252 in the binding pocket of mOR-EG. Eugenol and ethyl vanillin are shown in blue and pink, respectively, in top view of the bound mOR-EG structures. The mutational analyses show that Val109 senses the size of the ligand, while Phe252 is involved in antagonist recognition (see Katada, S. *et al.*, 2005 for more detail). Adapted from Katada, S., Hirokawa, T., Oka, Y., Suwa, M., and Touhara, K. 2005. Structural basis for a broad but selective ligand spectrum of a mouse olfactory receptor: mapping the odorant-binding site. J. Neurosci. 25, 1806–1815, Copyright 2005 by the Society of Neuroscience, with permission.

the fact that single amino acid changes caused predictable changes in agonist and antagonist specificity (Katada, S. *et al.*, 2005) (Figure 12). Thus, the stereospecific receptor theory was proven by the functional identification of the odorant-binding site, and it appears that ligand information is transduced by the three-dimensional configuration of the binding pocket and its specific odorant ligand.

4.30.4.5 Odorant Sensitivity and Specificity

The sensitivity of ORs to odorants in heterologous expression systems is relatively high compared to that in the olfactory system; specifically, the threshold concentrations for the best ligand in each OR range from a few to several hundred micromolar (Mombaerts, P., 2004). This is not simply due to problems of the

heterologous expression system because the sensitivity of olfactory sensory neurons expressing the same OR is similar (Oka, Y. *et al.*, 2004b; 2006) (Figure 13(a)). The odorant sensitivity of glomeruli innervated by olfactory neurons expressing a defined OR, however, is approximately 1000-fold higher than that of peripheral neurons (Oka, Y. *et al.*, 2006) (Figure 13(a)). In addition, the specificity of the in vivo odorant response in an OR-defined glomerulus is different from that suggested by the *in vitro* pharmacology in a heterologous system (Oka, Y. *et al.*, 2006) (Figure 13(b)). The higher apparent sensitivity and specificity to odorants *in vivo* seems to be due to a contribution of the olfactory mucosa, which provides a site for efficiently concentrating odorants and carrying them to the receptor site. An important caveat to this is that the ligand specificity of ORs in heterologous OR expression systems may not always reflect the specificity observed in the olfactory bulb *in vivo*.

4.30.5 Function II: Others

4.30.5.1 Axon Guidance

Olfactory sensory neurons expressing a given OR project their axons to defined glomeruli in the olfactory bulb (Ressler, K. J. *et al.*, 1994; Vassar, R. *et al.*, 1994; Mombaerts, P. *et al.*, 1996) (Figure 14). Receptor deletion or swapping experiments suggest that the OR protein itself is instructive for the guidance of olfactory neuron axons (Wang, F. *et al.*, 1998). Indeed, the OR proteins are present in olfactory axonal terminals (Barnea, G. *et al.*, 2004; Strotmann, J. *et al.*, 2004) as well as in cells of the cribriform mesenchyme, which are involved in fasciculation and sorting of outgrowing axons (Schwarzenbacher, K. *et al.*, 2006). A point mutation in the OR protein results in the formation of novel glomeruli, indicating that the OR amino acid sequence encodes information about axonal identity (Feinstein, P. and Mombaerts, P., 2004). The OR, however, is not

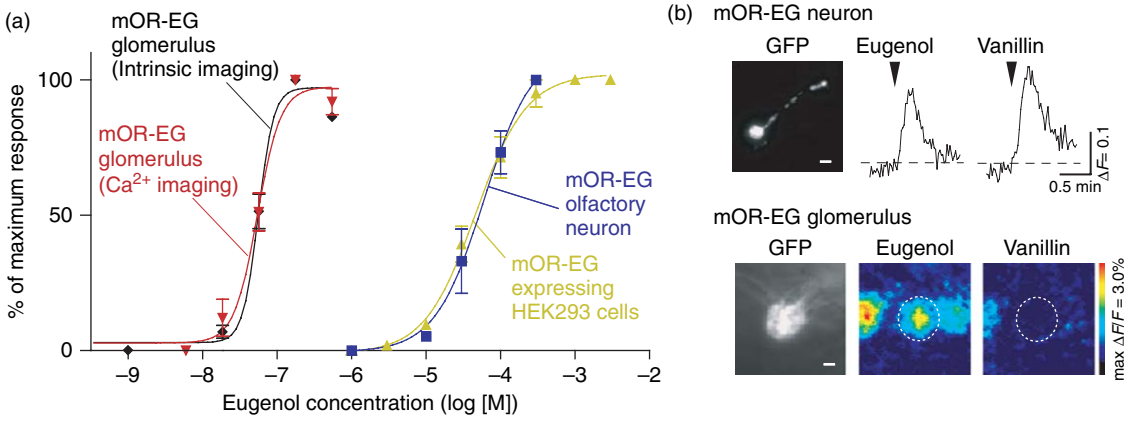

Figure 13 Different odorant sensitivity and specificity between olfactory neurons expressing mOR-EG and the corresponding mOR-EG glomerulus. (a) Dose–response analysis of mOR-EG *in vivo* and *in vitro*. The mOR-EG glomerulus exhibits higher sensitivity compared to the response properties determined in HEK293 cells or in mOR-EG-expressing neurons. (b) Odorant responses in mOR-EG-expressing olfactory neurons (upper panel) and in mOR-EG glomerulus (lower panel). The mOR-EG-expressing neurons showed responses to vanillin, whereas the mOR-EG glomerulus did not respond to vanillin (see Oka, Y. *et al.*, 2006 for more detail).

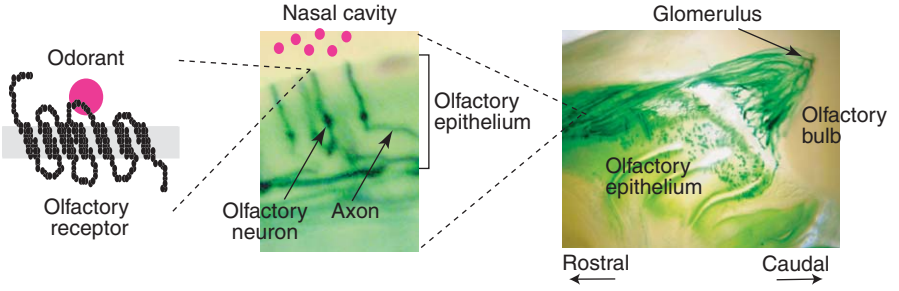

Figure 14 Fluorescent images of the olfactory epithelium and the olfactory bulb of gene-targeted mice expressing LacZ in mOR-EG-expressing olfactory neurons.

the only player in axonal convergence; membrane receptors such as the ephrin receptor and the neuropilin may be coordinately involved in determining the sensory map in the olfactory bulb (Pasterkamp, R. J. *et al.*, 1999; Cutforth, T. *et al.*, 2003). In addition, the instructive role in axon guidance is not restricted to an OR. Also, β2-adrenergic receptor can substitute for an OR in glomerular formation, suggesting that GPCRs have common functions (Feinstein, P. *et al.*, 2004). Both ORs and the β2-adrenergic receptor couple to the stimulatory G proteins, Gαs, which may account for the common functions of these receptors. In agreement with this, OR-mediated Gαs signaling has been shown to be one of the positional determinants (Imai, T. *et al.*, 2006). Thus, the OR proteins expressed on the olfactory neuronal cilia and dendrites recognize odorants from the external environment, whereas the same OR proteins localized on axon termini appear to function as key mediators of proper axon guidance.

4.30.5.2 Chemosensor

Analogous to axon guidance, wherein olfactory neurons are attracted and directed to a defined glomerulus by the ORs, testicular ORs are likely involved in proper navigation of sperm toward the egg in mammals (Spehr, M. *et al.*, 2006a). In sperm, human OR17-4 recognizes bourgeonal, a floral aldehyde odorant, resulting in induction of chemotaxis and chemokinesis (Spehr, M. *et al.*, 2003). Similarly, MOR23 expressed in mouse sperm recognizes the floral aldehyde odorant lyral, which regulates sperm motility (Fukuda, N. *et al.*, 2004) (Figure 15). Since both bourgeonal and lyral are synthetic fragrances, identification of the endogenous ligands for these ORs is necessary to demonstrate the biological relevance of sperm ORs. Multiple testicular ORs are expressed by various types of spermatids and spermatocytes in different developmental stages in mice, suggesting that some ORs are involved in spermatogenesis rather than in sperm physiology (Fukuda, N. and Touhara, K., 2006) (Figure 5). In any event, ORs may function as chemosensors in nonolfactory tissues.

4.30.5.3 Pheromone Detector

Pheromones are substances that are utilized for intraspecies communication (Karlson, P. and Luscher, M., 1959; Stowers, L. and Marton, T. F., 2005; Touhara, K., in press). In mice, pheromones are detected by two olfactory systems: the main olfactory system and the vomeronasal system (Halpern, M. and Martinez-Marcos, A., 2003; Baxi, K. N. *et al.*, 2006; Spehr, M. *et al.*, 2006b). Thus, the ORs in the main olfactory system recognize both odorants and volatile pheromones. In fish, ORs seem to play a role in recognizing putative pheromones such as bile acid, prostaglandin, and steroid derivatives (Friedrich, R. W. and Korsching, S. I., 1998; Sorensen, P. W. and Caprio, J., 1998; Luu, P. *et al.*, 2004). Similarly, some insect ORs are utilized as sex pheromone receptors (Nakagawa, T. *et al.*, 2005). In contrast to mammalian ORs, which function as monomers, formation of heterodimers is required for the function of ORs as pheromone sensors in insects (Nakagawa, T. *et al.*, 2005) (Figure 16). During evolution, each species

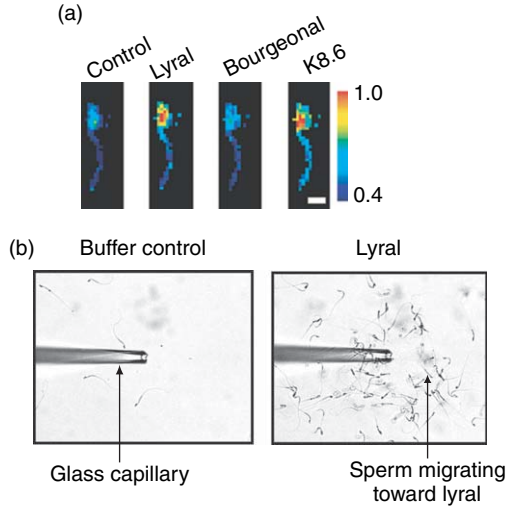

Figure 15 Responses of mouse sperm to lyral, a ligand for MOR23. (a) Pseudocolored image of Ca^{2+} levels in mature mouse sperm responding to lyral and K8.6. (b) Images of mouse sperm that show accumulation around the tip of a glass microcapillary containing lyral. Adapted from Fukuda, N., Yomogida, K., Okabe, M., and Touhara, K. 2004. Functional characterization of a mouse testicular olfactory receptor and its role in chemosensing and in regulation of sperm motility. J. Cell. Sci. 117, 5835–5845.

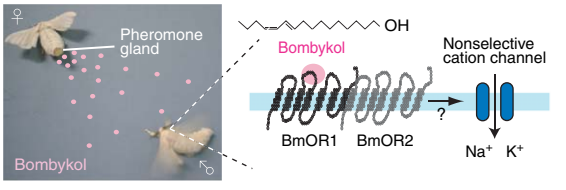

Figure 16 Responses of male silk moths to sex pheromone, bombykol, produced by female moths. Bombykol is recognized by a hetrodimeric complex of two olfactory receptors (ORs), BmOR1 and BmOR2, and elicits nonselective cation channel activity (see Nakagawa, T. *et al.*, 2005 for more detail).

selected an appropriate OR as a pheromone sensor, and the sensor has acquired unique signal transduction mechanisms, which provide high sensitivity and specificity for the target pheromone.

4.30.6 Remaining Problems

The discovery of the OR superfamily and subsequent experimental evidence validated the stereospecific receptor theory, which states that each functional group of an odorant is a molecular determinant for the odorant's interaction with an OR. The fact that the olfactory neuronal circuits follow the one-neuron one-receptor rule and OR-instructed axonal convergence suggests that a combinatorial receptor code for each odorant is transmitted to the olfactory bulb without the information being mixed.

Several questions remain to be answered. For example, how are OR proteins transported to the cilia? What is the mechanism mediating the negative feedback of OR expression? How is the zonal expression pattern formed? Is the presence of olfactory mucus crucial for the olfactory sensitivity and specificity? Is there an endogenous ligand for ORs expressed in nonolfactory tissues? Is the vibrational theory completely dead? How are small molecules such as CO_2 and H_2S recognized? What is the three-dimensional structure of an OR? What are the molecular dynamics of an OR upon ligand binding? Is there a relationship between OR polymorphism and anosmia? What are the differences in neuronal circuits between odorants with physiological effects and those without? Some of these questions will have been explored by the time that this review is in press, but there are always remaining questions because olfaction is the most mysterious of the senses.

Acknowledgments

I would like to thank the members of Touhara laboratory for providing data. This work was supported in part by grants from the Ministry of Education, Science, Sports, and Culture (MEXT), the Japan Society for the Promotion of Science (JSPS), and the Program for Promotion of Basic Research Activities for Innovative Biosciences (PROBRAIN) in Japan.

4.31.1 Organization and Structure of the Odorant Receptor Genes

A multigene family encoding odorant receptor (OR) molecules was first identified in rat, which consists of hundreds of related OR genes (Buck, L. and Axel, R., 1991). In humans, only ~350 of the 800 OR genes have an intact open reading frame and are assumed to be functional (Glusman, G. *et al.*, 2001; Malnic, B. *et al.*, 2004). In the mouse, of ~1400 OR sequences, some 20% are pseudogenes (Young, J. M. *et al.*, 2002; Zhang, X. and Firestein, S., 2002; Godfrey, P. A. *et al.*, 2004; Zhang, X. *et al.*, 2004a). The mouse repertoire of ~1100 functional OR genes is the largest multigene family that encompasses ~5% of all genes. Mouse ORs are grouped into ~230 subfamilies, based on the amino acid identities of >40% (Zhang, X. and Firestein, S., 2002). Vertebrate OR genes are divided phylogenetically into two different classes, I and II. The class I genes resemble the fish OR genes, while the class II genes are unique to terrestrial vertebrates. The mouse OR genes are clustered at ~50 different loci spread over almost all chromosomes. Each cluster contains 1–189 OR genes, with an average intergenic distance of ~25 kb. Most OR genes are composed of two to five exons, where usually one exon encodes the entire protein. At least two-thirds of OR genes exhibit multiple transcriptional variants with alternative isoforms of noncoding exons (Young, J. M. *et al.*, 2003). Comparative analysis of the mouse and human OR genes revealed that coding homologies within the clusters are accounted for by recent gene duplication as well as gene conversion among the coding sequences (Nagawa, F. *et al.*, 2002). To maintain the integrity of the domain structure of the olfactory sensory map, gene conversion may have played an active role in maintaining the sequence similarities between the paralogs of the OR genes.

4.31.2 Zone-Specific Expression of Odorant Receptor Genes in the Olfactory Epithelium

In rodents, the olfactory epithelium (OE) can be divided into at least four distinct zones, based on the expression patterns of OR genes (Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993; Strotmann, J. *et al.*, 1994a; 1994b). The most dorsomedial zone of the OE is defined as zone 1, according to the nomenclature of Sullivan S. L. *et al.* (1996). Zone 1 olfactory sensory neurons (OSNs) are positive for olfactory medium-chain acyl-CoA synthetase (O-MACS) (Oka, Y. *et al.*, 2003), but negative for olfactory cell adhesion molecule (OCAM) (Yoshihara, Y. *et al.*, 1997). Conversely, nonzone 1 OSNs are negative for O-MACS, but positive for OCAM.

4.31.2.1 Class I Odorant Receptors

The class I ORs were first identified in fishes (Ngai, J. *et al.*, 1993) and later found in amphibians (Freitag, J. *et al.*, 1995). They are assumed to recognize water-soluble odorous ligands. Class I ORs are also found in mammals, including human (Glusman, G. *et al.*, 2001; Malnic, B. *et al.*, 2004) and mouse (Zhang, X. and Firestein, S., 2002; Young, J. M. *et al.*, 2002; Zhang, X. *et al.*, 2004a; Godfrey, P. A. *et al.*, 2004). In the mouse, there are over 150 class I OR genes, classified into 42 subfamilies (Zhang, X. and Firestein, S., 2002; Zhang, X. *et al.*, 2004a). They are all clustered at a single locus on the mouse chromosome 7. A high-throughput microarray and *in situ* hybridization analyses revealed that almost all class I OR genes are expressed in zone 1 (Zhang, X. *et al.*, 2004b; Tsuboi, A. *et al.* 2006). It is possible that they are coordinately regulated by a common locus control region (LCR) and/or promoter sequences.

4.31.2.2 Class II Odorant Receptors

In contrast to class I, class II OR genes account for a large share of the mammalian OR repertoire. ISH analyses with various OR gene probes demonstrated that each OR gene is expressed in a restricted area in the OE. It has been reported that OSNs expressing a given OR gene are confined to one of the four OE zones but are randomly distributed within the zone (Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993; Strotmann, J. *et al.*, 1994a; 1994b). This appears to be true for zone 1-specific class I genes (Tsuboi, A. *et al.*, 2006). However, for most class II OR gene, the expression area is not always confined to one of the four conventional zones (Norlin, E. M. *et al.*, 2001; Iwema, C. L. *et al.*, 2004; Miyamichi, K. *et al.*, 2005). Expression areas appear to be specific to each OR gene and are arranged in an overlapping and continuous manner in the OE. It was demonstrated by DiI retrograde staining experiments that the dorsal/ventral arrangement of glomeruli in the olfactory bulb (OB) is well correlated with the expression areas of corresponding ORs along the dorsomedial/ventrolateral (DM/VL) axis in the OE (Miyamichi, K. *et al.*, 2005). How is the area-specific expression regulated for the OR genes? It has been assumed that zone-specific transcription factors for the OR genes are responsible for the regulation. However, if the expression areas of various ORs are arranged in a continuous and overlapping manner, we may have to consider an alternative mechanism, one that detects a gradient or the relative location in the OE for each OR gene along the DM/VL axis. If this is the case, the choice of the OR genes may be more restricted by the location of the OSN in the OE than what has been thought.

4.31.3 Single Odorant Receptor Expression in Each Olfactory Sensory Neuron

OSN axons expressing the same OR converge to a specific set of glomeruli in the OB. In the mammalian olfactory system, single OR gene choice and OR-instructed axonal projection are fundamental to the conversion of olfactory signals to a topographic map in the OB. Quantitative analysis of ISH led to the suggestion that each OSN expresses a limited member of OR gene, possibly one (Ngai, J. *et al.*, 1993; Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993). Subsequent cDNA analyses of a single OSN revealed that only one OR is expressed in each cell (Malnic, B. *et al.*, 1999). The first evidence for the one glomerulus–one receptor rule came from ISH of OB slices detecting OR mRNA at the axon termini within a glomerulus (Ressler, K. J. *et al.*, 1994; Vassar, R. *et al.*, 1994; Tsuboi, A. *et al.*, 1999; 2006). Each OR probe detected a pair of glomeruli, one glomerulus on the lateral and the other on the medial side of the OB. Subsequent studies using the marker-tagged OR gene allowed visualization of individual axons (Mombaerts, P. *et al.*, 1996; Wang, F. *et al.*, 1998). In such animals, all OSN axons expressing a given OR converge on a

specific set of glomeruli. Thus, odorant stimuli that have activated OSNs in the OE are converted to a topographic map of activated glomeruli, that is, an odor map in the OB (Uchida, N. *et al.*, 2000).

4.31.4 Allelic Exclusion of Odorant Receptor Genes

Autosomal genes come in two alleles, the paternal and maternal, and most of them are expressed biallelically. However, some are expressed monoallelically, for example, the antigen receptor genes and a few interleukin genes. Allelic exclusion was also observed in the OR gene system by using PCR to detect the polymorphisms in the transcripts from the paternal and maternal alleles of a particular OR gene (Chess, A. *et al.*, 1994). Gene-targeted mice, in which both alleles were differently tagged, have demonstrated the monoallelic expression of the OR gene (Strotmann, J. *et al.*, 2000): among thousands of cells examined, no OSN expressed both markers, simultaneously. Furthermore, the nuclei of OSNs were analyzed by fluorescent *in situ* hybridization (FISH) using OR gene probes (Ishii, T. *et al.*, 2001). RNA- and DNA-FISH were performed to detect the transcriptionally active site and the chromosomal location of the genomic sequence, respectively. In this experiment, DNA-FISH detected two genomic loci in the nuclei, one for the paternal and the other for the maternal allele, while RNA-FISH detected the primary transcripts at only one of the two genomic sites. Together, these results confirmed the monoallelic expression of the OR gene. Monoallelic expression of OR molecules appears to be quite important, not only in recognizing the ligand, but also in projecting axons to a specific site in the OB. If two different OR molecules were expressed from both alleles, this would cause confusion in the bundling and pathfinding of OSN axons.

Exclusion has also been found between the endogenous and the transgenic OR gene alleles, and even among the tandemly linked transgenic alleles with the same coding and promoter sequences (Serizawa, S. *et al.*, 2000). These studies demonstrate that under any circumstance, no more than one OR allele can be expressed in each neuron. Such an unusual mode of gene expression, monoallelic and mutually exclusive, has previously been shown only for the antigen receptor genes of the immune system.

4.31.5 Single Odorant Receptor Gene Expression

4.31.5.1 Positive Regulation

What kind of mechanisms would be possible to maintain the expression of only a single OR gene in each OSN? On the basis of previous studies on other multigene families, three activation mechanisms have been considered for the choice and activation of OR genes (Kratz, E. *et al.*, 2002):

1. DNA recombination, which brings a promoter and the enhancer region into close proximity;
2. gene conversion, which transfers a copy of the gene into the expression cassette; and
3. LCR, which interacts with only one promoter site.

Irreversible DNA changes, that is, recombination and gene conversion, have been attractive explanations for single OR gene expression because of the many parallels between the immune and the olfactory systems. However, two groups have independently cloned mice from postmitotic OSN nuclei, and found that the mice showed no irreversible DNA changes in the OR genes (Eggan, K. *et al.*, 2004; Li, J. *et al.*, 2004). Furthermore, these mice did not exhibit monoclonal expression of the OR in the donor OSN. Thus, the DNA rearrangement models for OR gene activation were finally excluded. Because the gene translocation models appeared unlikely, the third possibility was explored, a *cis*-acting DNA region, for example, LCR, that might regulate the expression of the OR genes. Sequence comparison of the mouse and human genomes revealed a 2 kb homology (H) region far upstream of the *MOR28* cluster (Figure 1) (Nagawa, F. *et al.*, 2002). Deletion of the H region abolished the expression of all OR gene members in the cluster on a yeast artificial chromosome (YAC) transgene (Serizawa, S. *et al.*, 2003). Furthermore, attachment of the H region to the truncated transgenic constructs lacking the upstream sequence restored the expression of the OR gene cluster (Serizawa, S. *et al.*, 2003). Interestingly, when the H region was relocated closer to the cluster, the number of OSNs expressing the proximal OR gene was greatly increased. This probably explains why the H region is located far from the OR gene cluster in the chromosome. If the H region were located too close to the cluster, the proximal OR gene would be activated frequently and the downstream genes would rarely be chosen. These results indicate that the H region is a *cis*-acting LCR that activates the *MOR28* cluster, although it is yet to be studied whether the LCR is commonly

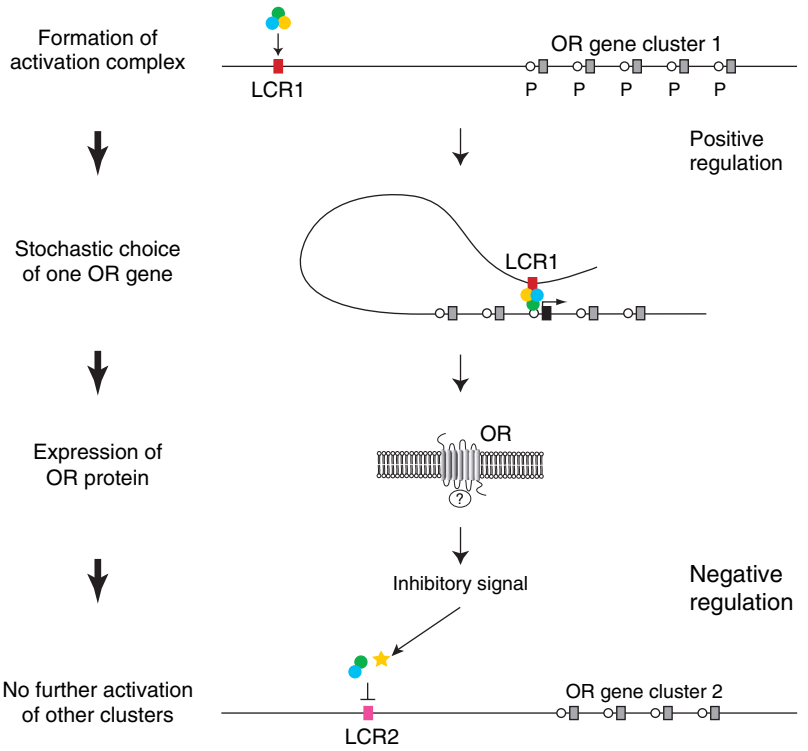

Figure 1 A model for the single odorant receptor (OR) gene expression. It is assumed that the activation complex formed in the locus control region (LCR) stochastically chooses one promoter (P) site by random collision, activating one particular OR gene member within the cluster (positive regulation). Once a functional gene is expressed, the OR molecules may transmit inhibitory signals to block the further activation of additional OR genes or clusters (negative regulation). Stochastic activation of an OR gene and negative feedback regulation by the OR gene product, together, can ensure the maintenance of the one receptor–one neuron rule in the mammalian olfactory system.

found in other OR gene clusters. In some transgenic experiments, a short stretch of DNA containing only the exons of the OR gene and its promoter are sufficient for the transgene to be expressed (Qasba, P. and Reed, R. R., 1998; Vassalli, A. *et al.*, 2002; Lewcock, J. W. and Reed, R. R., 2004). How does this happen? It is possible that these short DNA segments contain an enhancer or have integrated into a transcriptionally active region of chromatin, nearby another enhancer or LCR. It appears that two regulatory regions, LCR and promoter, cooperate in expressing the OR genes. It is possible that the chromatin-remodeling complex formed in the LCR activates the OR gene cluster, and that the LCR–promoter association initiates the transcription of the targeted OR gene (Figure 1).

4.31.5.2 Negative Regulation

It is important to ask how the expression of one particular OR gene is maintained. It appears that the activation complex formed in the LCR interacts with only one promoter site in the OR gene cluster (Figure 1), as has been reported for other gene systems, for example, the human visual pigment genes (Wang, Y. *et al.*, 1999; Smallwood, P. M. *et al.*, 2002) and globin genes (Li, Q. *et al.*, 1999). However, this would not preclude the activation of a second OR from the other allele or other OR gene clusters. To achieve mutually exclusive expression, negative feedback regulation may be needed to prohibit the further activation of other OR genes or OR gene clusters. It is known that a substantial number of pseudogenes are present in the mammalian OR gene families; ~20% of total OR genes in mouse (Young, J. M. *et al.*, 2002; Zhang, X. and Firestein, S., 2002; Godfrey, P. A. *et al.*, 2004; Zhang, X. *et al.*, 2004a) and ~60% in human are nonfunctional (Glusman, G. *et al.*, 2001; Malnic, B. *et al.*, 2004). In the scenario where the activated LCR has committed to a pseudogene, another LCR must undergo a similar process to ensure the activation of an intact OR gene. Once a functional OR gene has been chosen

and expressed, this trial must be halted. It has been proposed that the functional OR proteins may prevent further activation of other OR genes in the cell (Figure 2). Coexpression analysis of OSNs with the naturally occurring frameshift mutants supported the feedback mechanism (Serizawa, S. *et al.*, 2003) (Figure 2). Activation of secondary OR genes was also seen with transgenic OR genes lacking either the entire coding region (Serizawa, S. *et al.*, 2003; Feinstein, P. *et al.*, 2004; Lewcock, J. W. and Reed, R. R., 2004; Shykind, B. M. *et al.*, 2004) or the start codon (Lewcock, J. W. and Reed, R. R., 2004) (Figure 2). These observations suggest that the OR gene product – not mRNA but protein – has a regulatory role in preventing the secondary activation of other OR genes (Figure 2). How is this negative regulation achieved? In the antigen receptor genes, further V(D)J joining ceases as soon as a functional gene is generated, whereas rearrangement continues when the joining is unsuccessful (i.e., out-of-frame). For the Ig heavy-chain genes, the pre-B-cell receptor provides an inhibitory signal via spleen tyrosine kinase (Syk) (Schweighoffer, E. *et al.*, 2003) to preclude further rearrangement in the heavy-chain locus, possibly by changes in chromatin structure (Karasuyama, H. *et al.*, 1996; Chowdhury, D. and Sen, R., 2004; Goldmit, M. and Bergman, Y., 2004; Mostoslavsky, R. *et al.*, 2004). An analogous feedback regulation is postulated for OR gene expression; however, the exact nature of inhibitory signals and target molecules is yet to be discovered. In the feedback model, attempts to activate functional OR genes can continue in two classes of OSNs: those that have not yet activated any OR gene and those that have activated OR pseudogenes. This prevents a large fraction of developing OSNs from becoming receptorless. Other possible mechanisms have been proposed to ensure the monogenic expression of the OR gene. Among them, the oligogenic model assumes that the OR gene activation occurs stochastically in each OSN according to a Poisson distribution (Mombaerts, P., 2004). In this model, it is assumed that OSNs that do not express an OR cannot survive, and that those expressing two or more OR genes are actively eliminated (negative selection), possibly because of the confusion in bundling and pathfinding.

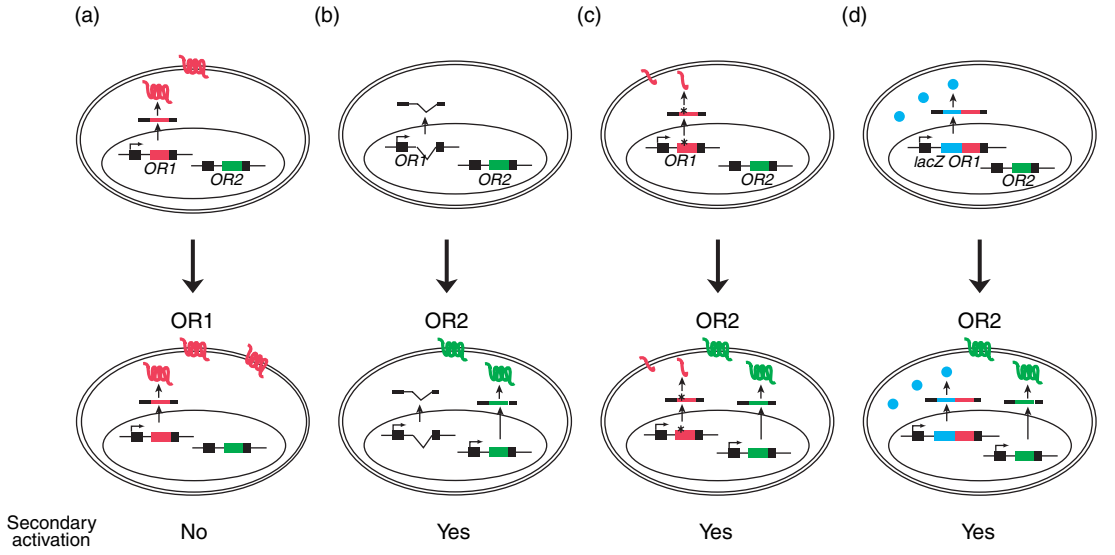

Figure 2 Inhibition of secondary odorant receptor (OR) gene activation by functional OR proteins. (a) Functional OR. When the activated OR gene (*OR1*) expresses functional OR proteins, activation of other OR genes (*OR2*) is inhibited. (b) Coding deletion (no OR). When the entire coding region is deleted, the activated mutant gene (*OR1*) cannot suppress the secondary activation of other OR genes (*OR2*). (c) Frameshift OR (short peptide). From the frameshifted pseudogenes, the full-length mRNA is synthesized. However, such pseudogenes express only short abnormal peptides because of premature stop codons created by frameshift mutations, and permit secondary activation of other OR genes (*OR2*). (d) The mRNA-alone construct (no OR). From this *lacZ–OR1* fusion gene, bicistronic mRNA is synthesized. Owing to the absence of the initiation codon in *OR1*, this mRNA produces only β-galactosidase (β-Gal). Because no OR1 protein is expressed, the secondary activation of other OR genes (*OR2*) is permitted.

4.31.6 *Cis*-Elements and *Trans*-Factors for Odorant Receptor Gene Expression

What kind of regulatory sequences and protein factors are needed for the single OR gene choice and zone-specific expression? Using full-length cDNA and 5′-RACE (rapid amplification of cDNA ends) analyses, conserved promoter sequences have been searched for in the OR gene system. However, no common promoter motifs were found for the 18 OR genes belonging to the *P2* cluster (Lane, R. P. *et al.*, 2001). Recently, based on the expression of transgenic minigenes, putative homeodomain, and Olf-1/EBF (O/E)-like binding sequences were identified in the immediately upstream regions of mouse, rat, and human OR genes including *MOR23*, *M71* (Vassalli, A. *et al.*, 2002), and *mOR37* (Hoppe, P. *et al.*, 2003). The homeodomain sequence was found to interact with a LIM-homeodomain protein, Lhx2 (Hoppe, P. *et al.*, 2003; Hirota, J. and Mombaerts, P., 2004), whereas the O/E-like motif is known to be recognized by O/E-1, -2, -3, and -4 helix–loop–helix transcription factors (Wang, S. S. *et al.*, 1997; 2002). Furthermore, the minimal promoter region for the *M71* gene expression has been defined with the transgenic minigene containing the homeodomain and O/E-like binding sequences (Rothman, A. *et al.*, 2005). Double mutations in both sites abolished the transgene expression. It has been proposed that the homeodomain and O/E sequences regulate the probability of *M71* gene choice differentially across the OE.

Recently, two competing gene loci in naive T helper (Th) cells, one for interleukin (IL)-4 on chromosome 11 and the other for γ interferon on chromosome 10, associate with each other via LCR in the IL-4 locus (Spilianakis, C. G. *et al.*, 2005). Such interchromosomal associations may not be restricted to the Th lymphokine system, but may instead underlie the general phenomenon of alternative gene regulation of multiple genetic loci, for example, the OR gene system. Because there are more than 50 different OR gene clusters scattered on many different chromosomes, the system needs to limit the number of activated clusters, ideally to one, to reduce the likelihood of the simultaneous activation of multiple OR genes. If the OR gene LCR can act interchromosomally like the IL-4 LCR, it would eliminate the need for every OR gene cluster to carry its own LCR (Lomvardas, S. *et al.*, 2006). Although it is yet to be clarified how many LCRs are present in the OR gene system, *trans*-acting LCR can contribute to the mutually exclusive activation of OR gene clusters scattered on many different chromosomes. Spatial organization of active chromatin structures and their cross talk within the nucleus may play key roles in regulating the coordinate expression of competing gene loci on different chromosomes.

4.31.7 Conclusion

In the mammalian olfactory system, each OSN activates only one functional OR gene in a monoallelic and mutually exclusive manner. Such unique expression forms the genetic basis for the OR-instructed axonal projection of OSNs to the OB (Imai, T. *et al.*, 2006; Serizawa, S. *et al.*, 2006). Thus, the one neuron–one receptor rule is essential for the conversion of olfactory signals received in the OE into a topographical map in the OB. One example of LCR has been reported for the mouse OR gene cluster which contains *MOR28*. Like the LCR in other gene systems, physical interaction between the LCR and the promoter probably enables the expression of only one OR gene within the cluster. This model is attractive because it reduces the likelihood of the simultaneous activation of two different OR genes, from a probability among ~1400 genes to that among ~50 loci. Recent transgenic experiments demonstrated that the mutant OR genes lacking either the entire coding sequence or the start codon can permit a second OR gene to be expressed. An inhibitory role has been postulated for the functional OR proteins to prevent the further activation of other OR genes, although the exact mechanism has yet to be elucidated. Stochastic activation of an OR gene by LCR and negative feedback regulation by the OR gene product, together, might ensure the maintenance of the one neuron–one receptor rule in the mammalian olfactory system.

4.32.1 Introduction

The *OR* gene superfamily is the largest multigene superfamily described in mammalian genomes. Surveys of the completed mouse genome sequence have indicated the existence of about 1068 potential intact *OR* genes (comprising at least 228 subfamilies) and 334 pseudogenes (Zhang, X. and Firestein, S., 2002; Zhang, X. *et al.*, 2004). In humans, there are ~350 intact *OR* genes and ~400 pseudogenes (Glusman, G. *et al.*, 2001; Zozulya, S. *et al.*, 2001; Niimura, Y. and Nei, M., 2003; Malnic, B. *et al.*, 2004). By way of contrast, molecular cloning and genomic DNA blot hybridizations in fish species suggest an *OR* repertoire size approximately five- to tenfold smaller than that of mammalian species (Ngai, J. *et al.*, 1993; Barth, A. L. *et al.*, 1997).

An understanding of how vertebrate olfactory receptor repertoires evolved can be gained from comparing the properties and organization of genes from divergent vertebrate species. In this regard, the zebrafish, *Danio rerio*, provides a useful model for comparative genomics studies, owing to intensive efforts to sequence this species' genome as well as a large research community using the zebrafish as a model experimental organism. In early studies, approximately 30 zebrafish *OR* sequences were identified previously using polymerase chain reaction (PCR) and homology-based techniques (Barth, A. L. *et al.*, 1996; Byrd, C. A. *et al.*, 1996; Weth, F. *et al.*, 1996; Barth, A. L. *et al.*, 1997; Vogt, R. G. *et al.*, 1997; Dugas, J. C. and Ngai, J., 2001). Although a number of phylogenetic reconstructions have been made (Freitag, J. *et al.*, 1995; 1998; 1999; Glusman, G. *et al.*, 2000; Dugas, J. C. and Ngai, J., 2001; Aparicio, S. *et al.*, 2002; Zhang, X. and Firestein, S., 2002; Irie-Kushiyama, S. *et al.*, 2004; Zhang, X. *et al.*, 2004), a more accurate view of the OR superfamily's evolutionary history would be facilitated by comparisons between genomic datasets that include a more complete representation of member genes from each species. To this end, genome database mining on the zebrafish genome sequence provided by the Sanger Institute *D. rerio* Sequencing Project has allowed a description of the complete *OR* gene repertoire in this species (Alioto, T. S. and Ngai, J., 2005; Niimura, Y. and Nei, M., 2005). An analysis of these receptor sequences and comparison with other vertebrate OR repertoires provide insights into the evolution of this chemosensory receptor superfamily in vertebrates.

4.32.2 The Zebrafish OR Repertoire

Iterative BLAST searches of the third (Zv3) and fourth (Zv4) draft zebrafish genome assemblies were conducted using previously identified ORs as query sequences (Alioto, T. S. and Ngai, J., 2005) (see also Niimura, Y. and Nei, M., 2005). This search identified 143 intact *OR* genes (136 with no disruptions), 7 partial genes, 10 pseudogenes greater than 700 bp in length, and 15 gene fragments shorter than 700 bp (Table 1). The total *OR* gene count is a conservative estimate of the true size of the OR repertoire, with between 78% (136/175) and 86% ([143 + 7]/175) of identifiable OR sequences consisting of potentially functional *OR* genes.

OR families are typically defined as monophyletic groups, with members that share greater than 40% amino acid identity, whereas subfamily members share greater than 60% amino acid identity (Lancet, D. and Ben-Arie, N., 1993). Using these operational

Table 1 Summary of identified teleost OR genes

	Zebrafish	*Fugu*	*Tetraodon*
Intact genes[a]	143 (7)	44 (3)	42 (6)
Partial genes[b]	7	9	4
Pseudogenes[c]	10	4	11
Total	160	57	57

[a]A gene is operationally defined as intact if it possesses a full-length OR protein coding sequence with no more than one disruption. For each species, the number of genes with a single disruption is listed in parentheses; the remainder contain no disruptions.
[b]A sequence encoding ≤275 contiguous amino acids, missing specific features characteristic of ORs (see the text for details), or missing start or stop codons is classified as a partial gene.
[c]A sequence is defined as a pseudogene if it is a partial gene with one or more disruption or a full-length gene with two or more disruptions.
From Alioto, T.S. and Ngai, J. 2005. The odorant receptor repertoire of teleost fish. BMC Genomics 6–173.

definitions, zebrafish *OR* genes were classified into families and subfamilies by reconstructing their phylogeny using neighbor-joining and maximum likelihood algorithms (Alioto, T. S. and Ngai, J., 2005). Clades of *OR* genes with less than ∼40% and less than ∼60% interbranch amino acid identity were used to group genes into distinct families and subfamilies, respectively. The average percent identity between families is approximately 25%, while the maximum observed percent identity between any two ORs of different families is 39% (Alioto, T. S. and Ngai, J., 2005).

4.32.3 Genomic Distribution of Zebrafish OR Genes

Previous studies have demonstrated that *OR* genes are clustered in vertebrate genomes (Ben-Arie, N. *et al.*, 1994; Dugas, J. C. and Ngai, J., 2001; Young, J. M. *et al.*, 2002; Zhang, X. and Firestein, S., 2002; Zhang, X. *et al.*, 2004). In mammalian genomes, *OR* genes are distributed widely, residing on 18 chromosomes in the mouse (Zhang, X. and Firestein, S., 2002) and 21 chromosomes in humans (Glusman, G. *et al.*, 2001; Malnic, B. *et al.*, 2004). From the zebrafish Zv3 and Zv4 assemblies, 119 of the identified zebrafish *OR* genes are distributed in five major clusters containing between 14 and 31 genes each (Alioto, T. S. and Ngai, J., 2005). There are two clusters on chromosome 15, two on chromosome 21, one on chromosome 10, several small clusters on chromosomes 8, 14, and 17, and in a few cases, genes exist as singletons (Figure 1). Genomic locations were assignable for ∼80% of the *OR* genes identified, with 29 remaining unassigned (Alioto, T. S. and Ngai, J., 2005). Subfamilies are largely contiguous, and subfamily members usually share the same transcriptional orientation, suggesting tandem duplication as a mechanism of expansion within a subfamily (Dugas, J. C. and Ngai, J., 2001; Kratz, E. *et al.*, 2002). The tight clustering of subfamily members in the zebrafish genome differs from the organization seen in mammalian genomes, which exhibit a higher degree of dispersion of related *OR* genes (Ben-Arie, N. *et al.*, 1994; Dugas, J. C. and Ngai, J., 2001; Young, J. M. *et al.*, 2002; Zhang, X. and Firestein, S., 2002; Zhang, X. *et al.*, 2004).

4.32.4 Phylogeny of Zebrafish OR Genes

A phylogenetic tree of the 143 intact *OR* genes and four full-length pseudogenes was constructed using a neighbor joining algorithm (Figure 2(a); Alioto, T. S. and Ngai, J., 2005). From this information, it is possible to discern the relationships between the OR genes and infer their evolutionary origins. Based on this analysis, zebrafish ORs could be classified into eight families (≥40% intrafamily sequence identity) and 40 subfamilies (≥60% intrasubfamily sequence identity). Most of the gene families contain between 12 and 40 genes each; the two smallest families, family A and family B, contain six genes and one gene each, respectively. The intrasubfamily identity threshold was lowered for three subfamilies, OR102, OR115, and OR125, to generate monophyletic clades. High bootstrap support (Figure 2(a)) justifies these classifications, with all subfamilies exhibiting bootstrap scores of 100%. In addition, the topology of the phylogenetic tree shown in Figure 2 is supported by an independent phylogenetic reconstruction using a maximum likelihood algorithm (Alioto, T. S. and Ngai, J., 2005).

4.32.5 Comparison of the Zebrafish, Mouse, and Pufferfish OR Repertoires

To gain additional insight into how the *OR* gene superfamily evolved in vertebrates, the zebrafish ORs were aligned to the set of OR sequences identified in the mouse genome (Alioto, T. S. and Ngai, J., 2005). Mouse ORs can be classified into two groups, class I and class II, each showing on average greater than 40% intragroup sequence identity (Zhang, X. and Firestein, S., 2002). Based on their greater similarity to the limited number of fish *OR* genes previously identified, class I genes from amphibians and mammals have been

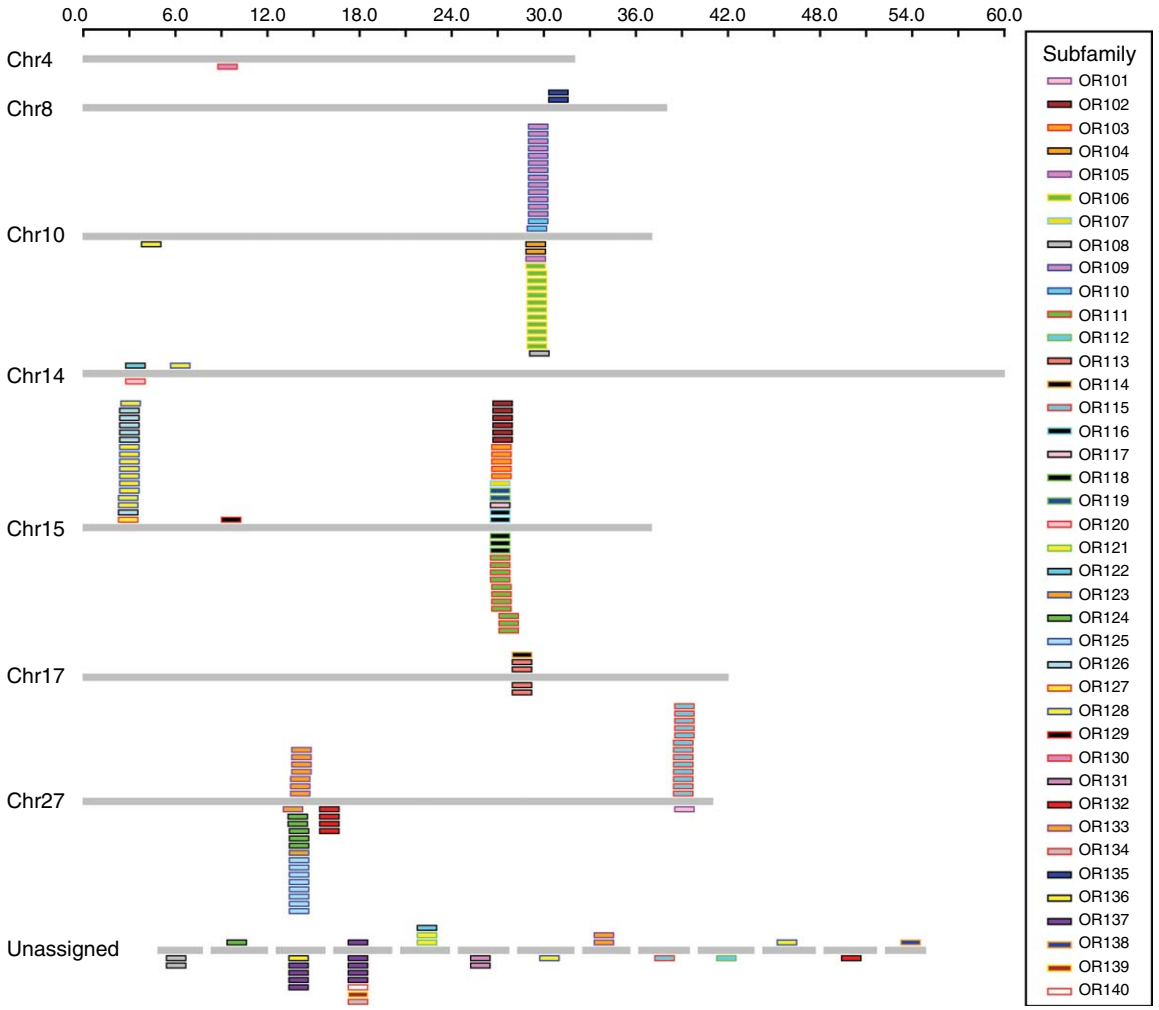

Figure 1 Chromosomal distribution of zebrafish *OR* genes. The majority of OR genes are organized in large clusters at only a few loci in the zebrafish genome. OR genes are depicted as boxes above (plus strand) or below (minus strand) a line representing each chromosome that encodes ORs. Genes are color coded according to subfamily. From Alioto, T.S. and Ngai, J. 2005. The odorant receptor repertoire of teleost fish. BMC Genomics 6, 173.

referred to as fish-like (Freitag, J. *et al.*, 1995; Glusman, G. *et al.*, 2001; Zhang, X. and Firestein, S., 2002). However, an analysis of the complete set of zebrafish *OR* genes indicates that this view cannot be generalized to the entire fish OR repertoire (Alioto, T. S. and Ngai, J., 2005). Mammalian class I and class II genes can in fact be grouped more closely with only two of eight approximately equidistantly related zebrafish families; class I genes show close similarity to only a small subset of zebrafish *OR* genes (*OR112-1*, *OR113-1*, *OR113-2*, and *OR114-1*, which together comprise family A), and one zebrafish gene (*OR101-1*, comprising the single member family B) clusters together with mammalian class II genes (Figure 2(b)). Overall, mouse class I exhibits similar average pairwise identity to the zebrafish families ($27.3 \pm 4.8\%$ identity (mean $\pm$ standard deviation); range: 17–32%) as mouse class II ($27.7 \pm 5.5\%$; range: 18–38%); the difference in mean values is not significant in a two-tailed *t*-test ($p = 0.89$).

A comparison with other teleost *OR* genes further reveals that six of the eight zebrafish OR families overlap with families from two pufferfish species, fugu (*Takifugu rubripes*) and tetraodon (*Tetraodon nigroviridis*) (Table 1 and Figure 2(c); Alioto, T. S. and Ngai, J., 2005). Families B and G do not appear to be present in the two pufferfish genomes. Interestingly, family H is clearly the most divergent family of teleost ORs (Figure 2(c); Alioto, T. S. and Ngai, J., 2005). The location of the outgroup melanocortin receptor between family H and the other families supports the

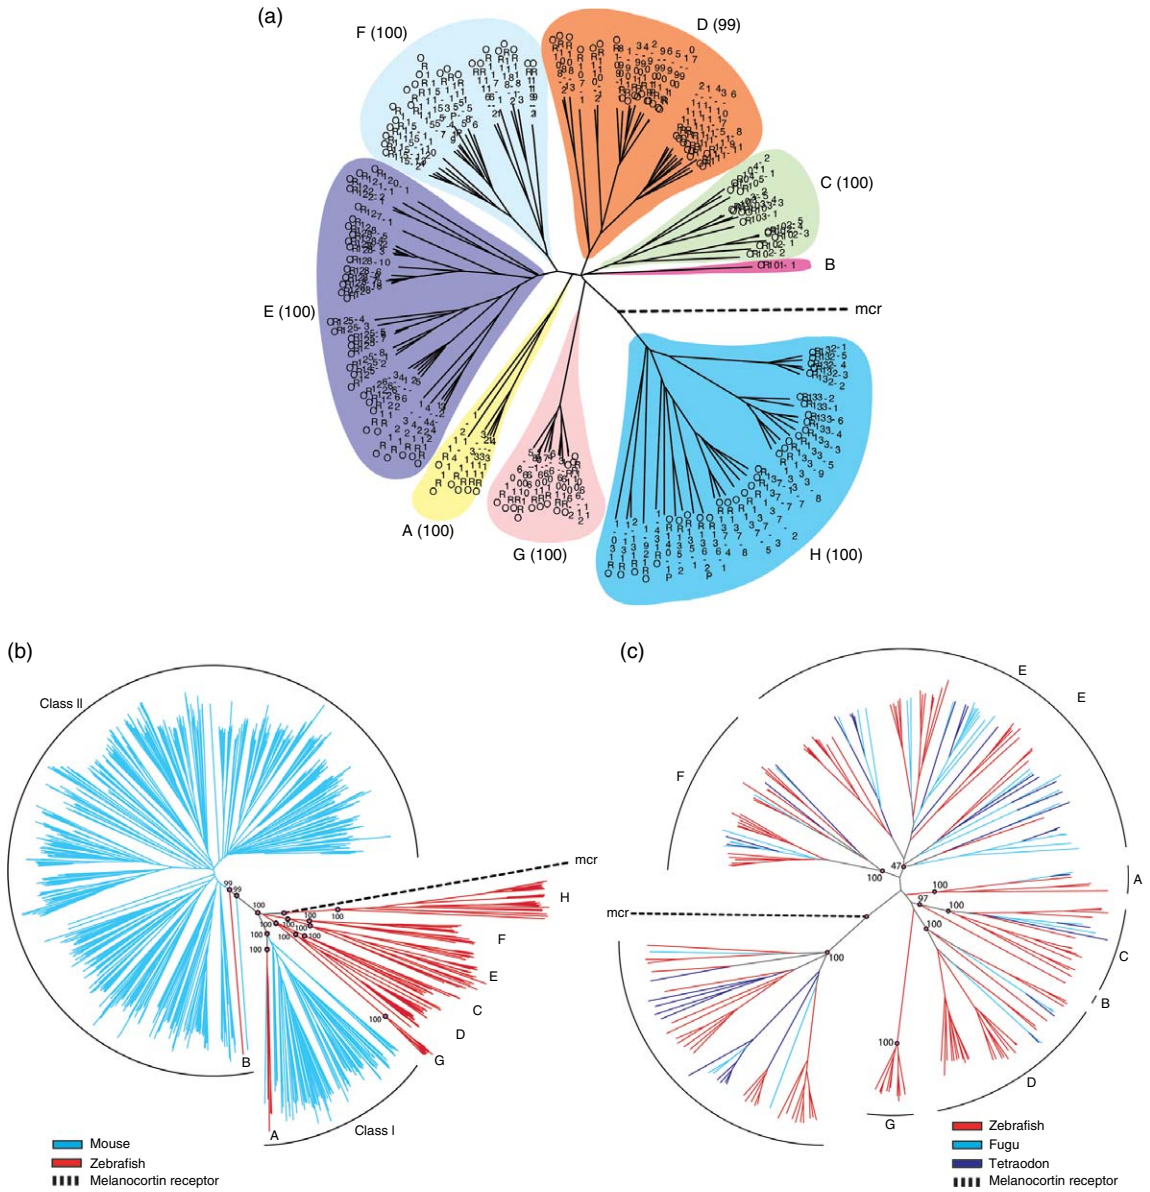

Figure 2 Phylogeny of zebrafish and other vertebrate OR families. (a) Phylogeny of zebrafish receptors. A neighbor-joining tree was constructed based on an alignment of the predicted amino acid sequences of 143 intact genes and four full-length pseudogenes identified from the zebrafish genome. *OR* genes are named by subfamily and colored by family. The eight gene families are labeled A–H. The zebrafish melanocortin receptor branch (dotted line labeled mcr) indicates the root of the tree. Bootstrap scores for each family are indicated in parentheses. (b) Phylogenetic relationship among zebrafish and mouse odorant receptors. The following sets of genes were aligned and used to construct a tree by neighbor joining: the mouse odorant receptors, mORs; the subset of 136 intact zebrafish ORs with no disruptions (highlighted in red); and mouse melanocortin receptors (mcr). Note the presence of *OR* gene subfamilies *OR112*, *OR113*, and *OR114* (family A) within the class I clade and zebrafish *OR101-1* (family B) within the Class II clade. Bootstrap scores corresponding to selected nodes are indicated. (c) Phylogeny of the complete OR repertoires of zebrafish, fugu and tetraodon. One hundred thirty-six nondisrupted genes from zebrafish, 42 nondisrupted genes from fugu, and 42 nondisrupted genes from tetraodon were used in this neighbor-joining analysis. Families are labeled A–H and correspond to the zebrafish families shown in panel (a). Bootstrap scores corresponding to selected nodes are indicated. From Alioto, T.S. and Ngai, J. 2005. The odorant receptor repertoire of teleost fish. BMC Genomics 6, 173.

conclusion that this family is the result of a very ancient gene duplication event. Based on the degree of divergence from other *OR* gene families, it is possible that the genes comprising family H may not in fact encode bona fide odorant receptors. However, family H forms a cluster distinct from non-OR G-protein-coupled receptors (GPCRs) in a phylogenetic tree comprising mouse and zebrafish ORs together with a set of 199 non-OR type I (rhodopsin class) mouse GPCRs (Figure 3). Thus, we consider the family H sequences operationally as *OR* genes. More generally, this phylogenetic reconstruction based on OR and non-OR GPCRs reveals that the ORs as a group are distinct from the other type I GPCRs.

4.32.6 Conserved Motifs in Predicted OR Protein Sequences

Previous studies of vertebrate ORs have identified a number of conserved sequence motifs characteristic of these receptors (Pilpel, Y. and Lancet, D., 1999;

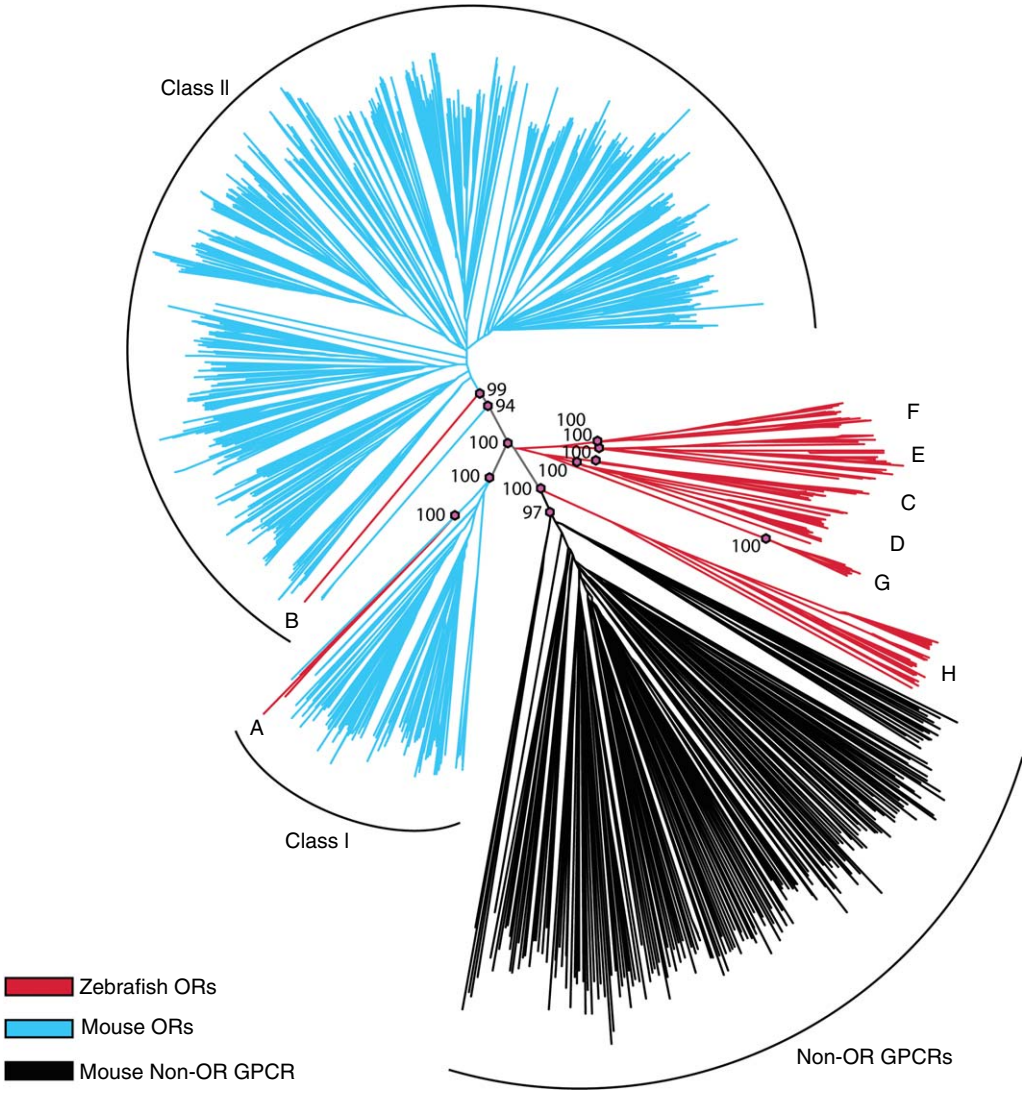

Figure 3 Phylogeny of zebrafish and mouse ORs rooted by mouse non-OR GPCRs. The following sets of genes were aligned: the mouse odorant receptors, mORs; the subset of 136 intact zebrafish ORs with no disruptions; and 199 mouse non-odorant rhodopsin-like GPCRs downloaded from GPCRDB (G-protein-coupled receptor database). A phylogenetic tree was then generated by neighbor joining. The expanded representation of non-OR GPCRs in this phylogeny more clearly demonstrates the segregation of OR and non-OR GPCRs as well as the approximately equal distance of zebrafish families C–H from the mouse class I and class II OR genes. From Alioto, T.S. and Ngai, J. 2005. The odorant receptor repertoire of teleost fish. BMC Genomics 6, 173.

Zozulya, S. *et al.*, 2001; Zhang, X. and Firestein, S., 2002). These include the following: an N-linked glycosylation site NX[TS]X in the N-terminal domain; the motif MA[FY][DE]RYVAIC located at the third transmembrane domain (TM3)/second intracellular loop (IC2) junction which is thought to interact with G-proteins (specifically G_{olf}); three conserved cysteine residues in the second extracellular loop (EC2) thought to partake in disulfide bonding; and the motif KAFSTCXSH in IC3 containing an intracellular cysteine conserved in GPCRs and potential phosphorylation sites. These motifs are conserved in all the zebrafish *OR* families, with the exception of Family H, in which only the MAYDRYVAIC motif is conserved. This sequence conservation is illustrated by a sequence logo generated from the alignment of predicted full-length zebrafish OR coding sequences (Figure 4(a); Alioto, T. S. and Ngai, J., 2005). In this representation, the relative frequency with which an amino acid appears at a given position is reflected by the height of its one-letter amino acid code in the logo, with the total height at a given position proportional to the level of sequence conservation. Interestingly, when compared to the sequence logo representing the alignment of mouse class I and class II ORs (Figure 4(b)), the zebrafish OR logo shows lower conservation

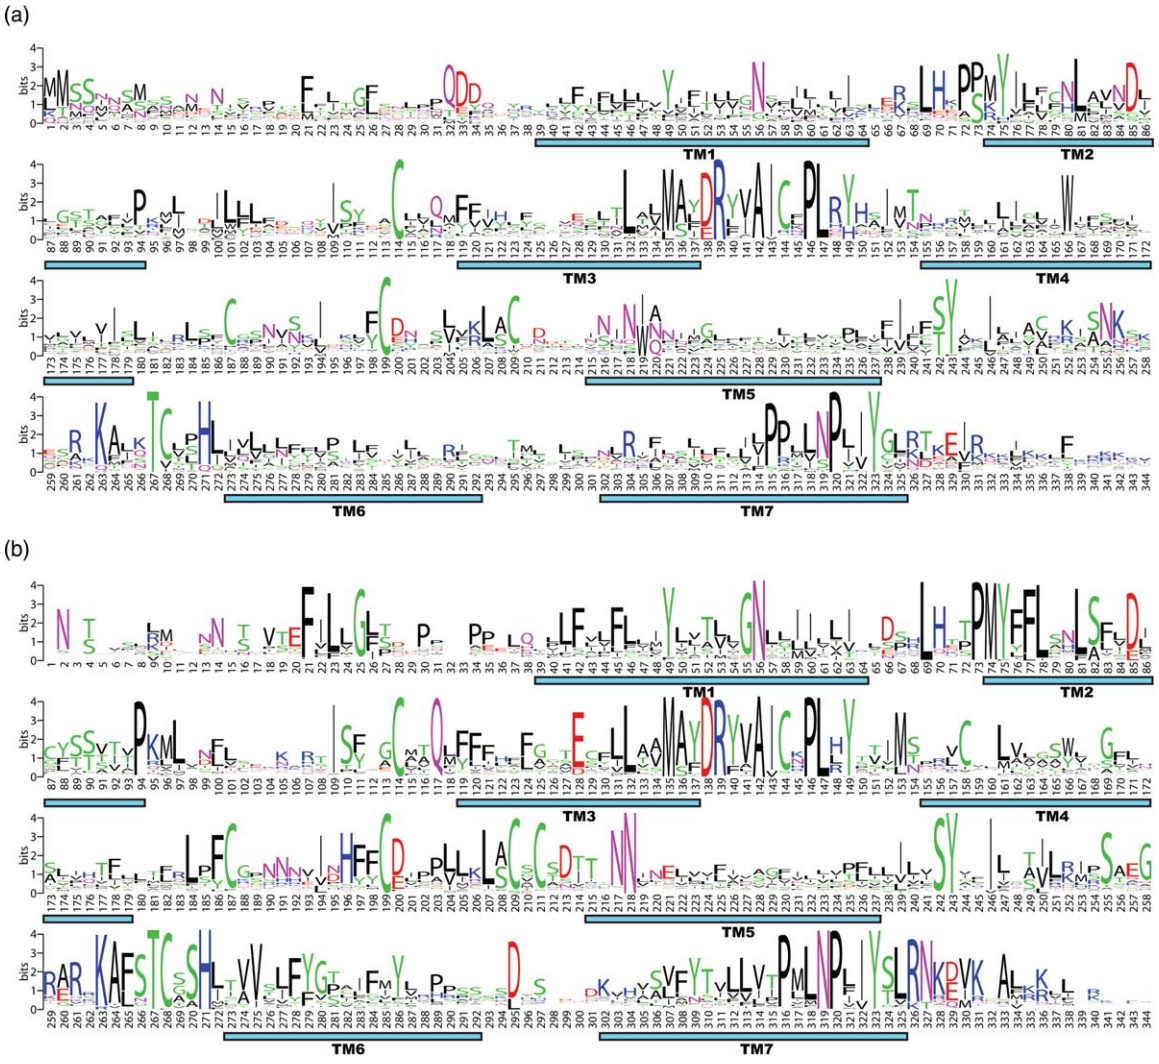

Figure 4 Sequence logos of zebrafish and mouse OR families. Conservation of predicted amino acid sequence for the zebrafish (a) and mouse (b) OR repertoires is shown graphically (see the text). *Y*-axis, information content. *X*-axis, residue position. For this analysis, positions with gaps in more than 95% of sequences, as well as poorly aligned N- and C-terminal sequences, were removed. Positions in the species-specific logos are identical according to this alignment. From Alioto, T.S. and Ngai, J. 2005. The odorant receptor repertoire of teleost fish. BMC Genomics 6, 173.

amongst the predicted zebrafish receptor sequences (reflected by the more numerous and shorter letters at individual positions in the logo), revealing the greater diversity within the zebrafish versus mouse OR superfamily (Alioto, T. S. and Ngai, J., 2005).

4.32.7 Evolution of the Vertebrate OR Gene Repertoire

The characterization of the complete *OR* repertoires from both fish and mammalian species allows an informed analysis of *OR* gene evolution in the vertebrate lineage. From the comparative analysis of mammalian and teleost OR sequences, a model for OR gene evolution in vertebrates can be proposed (Alioto, T. S. and Ngai, J., 2005): *OR* genes in present-day vertebrates likely descended from eight ancestral *OR* genes (or gene families) that existed at the time of the split between ray-finned and lobe-finned fish (the ancestors of teleosts and tetrapods, respectively) approximately 450 million years ago (Hedges, S. B., 2002). A phylogenetic reconstruction based on mouse and zebrafish ORs and 199 mouse non-OR GPCRs (Figure 3) indicates that the ORs form a group distinct from all other type I GPCRs, possibly reflecting a very ancient duplication event(s) and/or rapid divergence of the ORs in the evolution of type I GPCRs. The estimate of ancestral *OR* gene number is based on the identification of eight *OR* gene families in teleosts, two of which show somewhat higher similarity to the two *OR* gene families in mammals. The grouping of zebrafish and pufferfish *OR* genes into common families indicates that the gene duplication events that gave rise to the major OR families probably occurred prior to the speciation of teleosts. In addition, the greater similarities between zebrafish family A and mouse class I, and between zebrafish family B and mouse class II, infer that the ancestral genes for these families existed before the tetrapodon/teleost split. Our model therefore suggests a history during which ancestral genes or gene families were selectively lost during the evolution of the different vertebrate lineages (Figure 5). Of the ancestral families, zebrafish retained eight families, fugu and tetraodon retained six families, and mammals retained two families.

It is also possible that the four to six gene families unique to teleosts descended from family A/class I and/or family B/class II ancestral genes, after the tetrapodon/teleost split. Such a scenario seems unlikely, however, considering the roughly equivalent

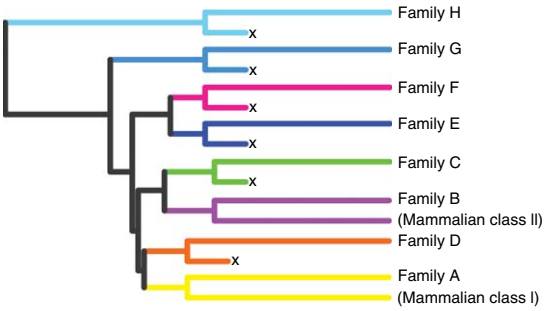

Figure 5 Model for vertebrate *OR* gene family evolution. We hypothesize the existence of a minimum of eight ancestral *OR* genes or gene families at the time of the last common ancestor between the tetrapodon and fish lineages. The phylogeny of OR families can be explained by differential family and subfamily expansion and gene death (X's on mouse lineages). Mammalian class I and class II represent a large expansion of two of these major OR families, each of which also encompasses zebrafish *OR* genes. Branch lengths not drawn to scale.

degree of divergence exhibited between seven of the eight teleost gene families (including family A and family B). Moreover, amphibian and avian OR genes can be grouped into six of the eight identified OR families (family A/class I, family B/class II, family C, family E, family F, and family H), further implicating the presence of common ancestral genes for these families prior to the tetrapodon/teleost split (Niimura, Y. and Nei, M., 2005).

Mechanisms of gene or family loss in a particular vertebrate lineage may have involved a number of processes, for example, gene conversion, pseudogenization of all genes in a family, unequal crossover recombination events during meiosis, or larger chromosomal rearrangements. From the available data, it is not possible to infer the precise order and rate of *OR* gene family expansion and contraction, or speciation events. Nonetheless, six of the retained *OR* gene families were subject to a substantial net expansion and diversification in zebrafish (and to a lesser degree in the pufferfish), while the other two ancestors gave rise to the present-day mammalian class I and class II ORs as well as to a small number of zebrafish genes. We hypothesize that relaxed selective pressure on a subset of the ancestral tetrapodon OR repertoire led to the loss of major *OR* gene families in the mammalian lineage. The expansion within the two remaining gene families was likely driven by the adaptation to the terrestrial odorous environment. Thus, different selective pressures found in the aquatic and terrestrial environments led to different sizes and shapes of the OR repertoires of fish and mammals.

It is generally thought that the diversity of OR sequences – as represented in the number of receptor families – underlies the diversity of chemical structures or odor space that can be detected by an organism's olfactory system. Thus, with approximately six to eight *OR* gene families retained over evolutionary time (vs. two in mammals), fish may be capable of detecting a larger diversity of chemical structures than mammals. However, the larger total number of OR sequences in mammals (~1000 vs. ~100 in fish) presumably allows a finer discrimination amongst the compounds that are detected by the mammalian olfactory system.

Glossary

gene A segment of DNA that represents a fundamental unit of heredity.

gene cluster Set of two or more related genes physically located nearby in the genome and encoding similar proteins.

genome The complete genetic content of an organism.

G-protein-coupled receptor (GPCR) Superfamily of seven transmembrane proteins functioning in signal transduction cascades including odorant/taste receptors, photoreceptors, dopamine receptors, acetylcholine receptors, and opioid receptors.

insect Arthropods with three pairs of legs and three body parts.

invertebrate Heterogenous cluster of animals based on their lack of internal skeleton including protozoa, annelids, echinoderms, mollusks, and arthropods.

locus Specific chromosomal location of a gene in the genome.

nematode Commonly known as roundworms based on their worm-like appearance.

odorant Chemical compound stimulating the olfactory system.

odorant-binding protein Small water-soluble proteins thought to bind odorants.

odorant receptor Subclass of membrane proteins belonging to the GPCR superfamily displaying affinity to various odorants.

olfaction Sense of smell.

ortholog Two genes in two separate species that derived from a common ancestral gene by speciation.

sensillum Morphological unit consisting of sensory neurons and accessory cells located on the surface of sensory tissues.

signal transduction Cellular process consisting of converting a signal into another. It is supported by a cascade of molecular components including receptors, enzymes, and ion channels.

synteny Describes the conserved arrangement of genes between related species.

4.33.1 Introduction

The diversity of the animal lineages and their adaptations to various environments are a testament to the formidable natural creativity of life. Within the context of the requirement for mobility, constraints such as gravity have been addressed differently across phyla: while some organisms escape immobility through the use of 2, 4, or 1000 legs, others choose to fly or crawl. In a similar context we may ask the question: how have the challenges of olfaction been answered in phylogenetically diverse phyla?

Olfaction is of fundamental importance in the life cycle and life histories of invertebrates such as insects, crustaceans, or round worms and has been described as the chemosensory modality dedicated to the detection of small airborne chemicals called odorants. Several observations challenge this definition. Aquatic animals use anatomically and molecularly similar chemosensory systems to detect low molecular weight, water-soluble compounds, blurring the distinction between olfaction and gustation. More compelling is the fact that, in general terms, the biochemistry of chemical recognition (chemosensation), that is, the initial physical interactions between the organism olfactory machinery and the environmental stimulus, occurs in a uniformly water-soluble medium. Accordingly, although the distinctive characteristics of gustatory and olfactory processes remain to be determined, the olfactory system must achieve four fundamental requirements that may best be summarized as: speed, tuning breadth, discrimination, and sensitivity. These elements represent the fact that within a few milliseconds, the organism must recognize and discriminate low-concentration odorants amongst a potentially unlimited set of qualitatively different chemical stimuli.

These requirements are even more salient among invertebrates that typically rely on olfaction as their main sensory modality. Experimental expediency and the relative simplicity of invertebrates compared to vertebrates have fostered the study of model organisms such as insects, crustaceans, and nematodes to advance our understanding of the underlying molecular and cellular mechanisms of olfaction. On the surface, the organization and the physiology of the chemosensory systems of arthropods and nematodes vary widely. Are these differences solely a reflection of genetic variability or do they derive from conserved principles? From the early 1980s to late 1990s, several olfactory components had been identified by biochemical and genetic extraction methods. However, the bulk of olfactory genes remained largely uncharacterized especially in the case of highly divergent gene families for which a homology-based approach proved inadequate. The availability of whole genome sequence of *Caenorhabditis elegans* and *Drosophila melanogaster* would change the equation forever (Consortium, C. E. S., 1998; Adams, M. D. *et al.*, 2000) to allow the analysis of large amounts of data and to facilitate the identification of olfactory gene families (Table 1). Importantly, many candidate olfactory genes are still to be functionally validated while others with unknown function remain unidentified. In this context, it is noteworthy that much of the work on invertebrate olfaction has been driven by visual and olfactory system studies in mammals.

What are olfactory genes and how many are there in any given organism? What are their functions? How and when do these gene families interact to generate complex phenotypes? The genomic era is still in its infancy, but it has already opened tremendous opportunities to study these questions. As more genomes become available, comparative genomics will likely reveal how chromosomal organization and rearrangements affect the nascent divergence of phylogenetically related species. Of particular interest is the analysis of orthologous genes across diverse taxa. Although at present, the olfactory genomics of invertebrates is limited to a handful of phylogenetically distant organisms, entire orthologous gene families have nevertheless been identified facilitating the elucidation of function using reverse genetic tools or by functional inference in several instances.

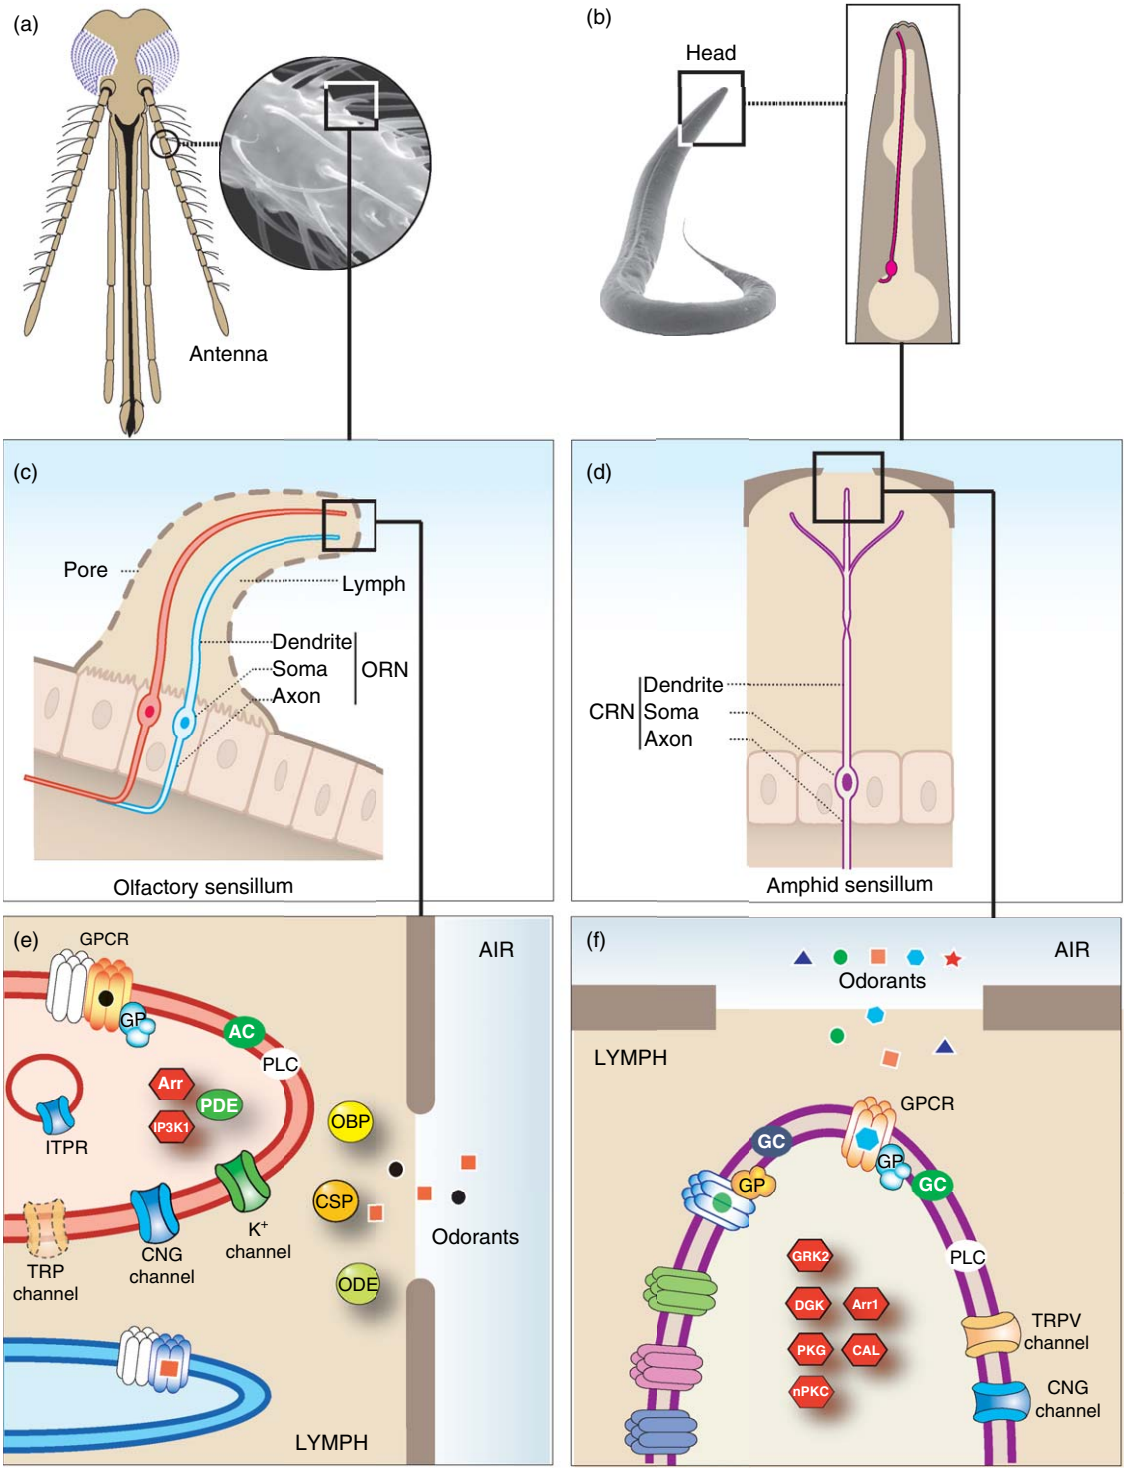
Numbers on the left indicate genes with putative olfactory functions and numbers on the right indicate functionally characterized genes. Genes with putative olfactory function are indicated by an asterisk* and unidentified family are indicated by ND (nondetermined). RGS, regulator of G protein signaling; Tm, transmembrane.

This chapter will discuss the current state of knowledge of gene families involved in odor reception, olfactory transduction, and adaptation. It will mainly draw from the study of three best-described invertebrate genomes: *D. melanogaster*, *Anopheles gambiae*, and *C. elegans*. We have included a brief comparative description of the cellular and the molecular participants in the invertebrate olfactory organs. A more detailed discussion of invertebrate olfactory systems is described in chapter 22. We structured our discussion to mimic the successive stages of primary olfactory sensing and adaptation, beginning with odor recognition, olfactory transduction and ending with regulation of primary sensory processing, as we review the organization, structure, regulation, and function of olfactory genes in insects and nematodes.

4.33.2 An Overview of Invertebrate Chemosensory Organs and Their Molecular Components

In insects, olfaction is mediated by thousands of primary olfactory receptor neurons (ORNs) segregated by groups of two or more in small olfactory organs called sensilla (Figure 1). The dendrites of these neurons project in perforated hollow cuticular structures of various morphological types and are mainly arrayed on the antennal surface. In *C. elegans*, volatile chemicals are detected by five pairs (AWA, AWB, AWC, ASH, and ADL) of chemoreceptor neurons (CRNs) located in the main sensory organs known as the amphid sensilla (Bargmann, C. I. *et al.*, 1993). These organs sit on each side of the buccal cavity and communicate with the external environment via a

prominent pore. Each CRN responds to many different compounds (Bargmann, C. I. and Horvitz, H. R., 1991). Despite overall morphological similarity, it is becoming more and more apparent that morphological differences result from ecological adaptations rather than based on olfactory-related requirements. In the case of the terrestrial giant robber crab, olfactory receptors (aesthetascs) display morphological and



physiological attributes intermediate between marine crustaceans and insects (Stensmyr, M. C. *et al.*, 2005). Drosophila olfactory sensilla exhibit over a dozen morphological subtypes, which do not seemingly relate to olfactory function (Shanbhag, S. R. *et al.*, 1999; Stocker, R. F., 2001).

Despite the diverse morphologies, the partitioned nature of these structures remains invariant between insects, crustaceans, and nematodes and represents a defining hallmark of invertebrates. Thus, it is not surprising that similar adaptive features are reflected by common cellular and molecular strategies. Olfactory sensilla are highly specialized cell clusters encased in the olfactory epithelium such that the ORNs are separated and protected from the environment by an aqueous fluid on its apical side and physiologically supported by accessory cells on its basal side. The physical and biochemical demands imposed by this system require an odorant to cross the extracellular sensillum lymph to reach the molecular receptor located on the surface of the dendritic membrane in order to activate the intracellular transduction machinery. Furthermore, another defining specificity is that insect odorant receptors (ORs) almost certainly require the association with a heterodimer partner homolog (Benton, R. *et al.*, 2006) for proper activation of intracellular downstream effectors such as a heterotrimeric G protein (GP) (Laue, M. *et al.*, 1997) and a cyclic nucleotide-gated (CNG) ion channel (Baumann, A. *et al.*, 1994; Dubin, A. E. and Harris, G. L., 1997).

Studies in cockroach, Drosophila, and lobsters implicate both a GP-coupled adenylyl cyclase (AC) and a GP-coupled phospholipase C (PLC) transduction cascades in olfactory reception (Boekhoff, I. *et al.*, 1990a; 1990b; Boekhoff, I. *et al.*, 1994; Riesgo-Escovar, J. *et al.*, 1995; Deshpande, M. *et al.*, 2000; Martin, F. *et al.*, 2001). Putative targets of these effector genes include a CNG channel and a cyclic nucleotide-modulated K^+ channel (Baumann, A. *et al.*, 1994; Dubin, A. E. *et al.*, 1998). Signal termination appears to be mediated by several enzymes including a cyclic adenosine monophosphate (cAMP)-phosphodiesterase (cAMP-PDE), an inositol 1,4,5-triphosphate kinase 1 (IP3K1), and two sensory arrestins (ARRs) (Martin, F. *et al.*, 2001; Merrill, C. E. *et al.*, 2002; 2003; Gomez-Diaz, C. *et al.*, 2004; Merrill, C. E. *et al.*, 2005; Gomez-Diaz, C. *et al.*, 2006). Regulation of GP signaling requires a transient receptor potential (TRP) Ca^{2+} channel (Bergamasco, C. and Bazzicalupo, P., 2006) and an inositol 1,4,5-triphosphate receptor (ITPR).

Rapid ORN activation depends on cellular and molecular mechanisms that facilitate the transport and the clearance of biologically active/toxic compounds. Although G-protein-coupled receptors (GPCRs), also known as seven-transmembrane receptors, and their GP partners are invariably used as ORs across diverse phyla, there is significant variation as to how these receptors interact with their molecular environment. Within invertebrate lineages, the main difference between arthropods and nematodes consists of divergent molecular strategies upstream of the GPCRs within the fluid compartment of the sensillum. Insect ORs interact with an extracellular perireceptor pathway that potentially includes various odorant-binding protein (OBP) members, possibly chemosensory proteins (CSPs) and odorant-degrading enzymes (ODEs).

ODEs comprise members of the cytochrome P450s, gluthatione-*S*-transferase and carboxylesterases supergene families that have often been implicated in olfactory signaling based on inferential expression patterns. In particular, in mosquitoes and other insects, ODEs play an important role in insecticide metabolism/resistance (Ranson, H. *et al.*, 2002), and several reports have suggested a possible

Figure 1 Comparison of the olfactory systems of arthropods and nematodes. (a)The antenna of a mosquito and (b) the head of *Caenorhabditis elegans* are magnified in (c) and (d), respectively, to show the cellular organization of insect olfactory sensillum and amphid sensillum. Two odorant receptor neurons (ORNs) and only one of the chemoreceptor neuron (CRN) are shown for clarity purposes. Close up of the dendritic termini are shown in (e) and (f) to show the various molecular components involved in olfactory sensing in both invertebrate systems. The molecular components of odor reception include the bona fide odorant-activated G-protein-coupled receptors (GPCRs). An additional role in odor coding has been proposed for the insect odorant binding proteins (OBPs) and chemosensory proteins (CSPs). Heterotrimeric G proteins (GPs) activate a variety of intracellular signal transduction pathways. Two main intracellular signaling routes are mediated by a phospholipase C (PLC) and adenylyl/guanylyl cyclase (AC and GC). These effector proteins target various receptors and ion channels such as an inositol triphosphate receptor (ITPR) and transient receptor potential (TRP), cyclic nucleotide-gated (CNG) potassium (K^+) channels. Regulation of GP/GPCR signaling is mediated by arrestins (ARR) and G protein-coupled receptor kinases (GRK). Calcineurin (CAL), protein kinases G and C (PKG, nPKC), and diacyl glycerol kinases (DGKs) modulate primary sensing by targeting various components of the transductory cascade. Picture of the *C. elegans* was kindly provided by Z. Altun and D. Hall.

role for ODEs in xenobiotic/odorant clearance based solely on their expression in olfactory tissues (Hovemann, B. T. *et al.*, 1997; Rogers, M. E. *et al.*, 1999; Maibeche-Coisne, M. *et al.*, 2005; Lycett, G. J. *et al.*, 2006). Owing to this paucity of specific data tying these genes to olfactory signaling, an in-depth analysis of ODEs superfamilies has not been included in this chapter. A review of ODEs is available from Vogt R. G. (2003).

For expediency we will focus on the chemosensory gene families in *C. elegans* restricted to the AWA, AWB and AWC neurons, which together mediate chemotaxis to a range of volatile attractants. A detailed review of the full chemical sensitivity in *C. elegans* is available from Bergamasco C. and Bazzicalupo P. (2006). Interestingly, no OBPs, CSPs, or ODEs have been described in nematodes (Rubin, G. M. *et al.*, 2000). The transduction pathways of *C. elegans* and insects are generally similar as they both use GPCRs and GPs (Zwaal, R. R. *et al.*, 1997; Roayaie, K. *et al.*, 1998; Lans, H. *et al.*, 2004) to target, in some cases, homologous ion channels (Colbert, H. A. and Bargmann, C. I., 1995; Tobin, D. *et al.*, 2002). However, *C. elegans* seems to favor cyclic guanosine monophosphate (cGMP) over cAMP as a second messenger (Birnby, D. A. *et al.*, 2000; L'etoile, N. D. and Bargmann, C. I., 2000). Moreover, the regulation of GP signaling in *C. elegans* involves several protein kinases (L'etoile, N. D. *et al.*, 2002; Fukuto, H. S. *et al.*, 2004; Okochi, Y. *et al.*, 2005; Matsuki, M. *et al.*, 2006), a single ARR and calcineurin (Kuhara, A. *et al.*, 2002; Palmitessa, A. *et al.*, 2005).

4.33.3 Odor Recognition

Upon entering the sensillum, an odorant is presumed to transverse the sensillum lymph in order to activate the OR. While this process is the initial component of odor recognition in arthropods and worms, the precise mechanisms and functional roles of molecular players such as OBPs and CSPs remain unclear. Nevertheless, these gene families have been proposed to play significant roles in the general process of perireception, that is, interaction of an odorant with molecular components preceding OR activation. Indeed, *Ors*, *Obps*, and *Csps* are ancient and diverse gene families, which are likely a reflection of their evolutionary value in olfactory signal transduction.

4.33.3.1 Insect Odorant-Binding Proteins

The OBP designation derives from their initial discovery in the silk moth *Antheraea polyphemus* where the first pheromone-binding protein (*Apol*PBP) was shown to bind *in vitro* one of the female sex pheromone component in the aqueous lymph bathing the pheromone-sensitive neuron (Vogt, R. G. and Riddiford, L. M., 1981). Membership in this gene family is contingent on the following four requirements: antennal-specific expression, putative odor-binding capability, overall size of approximately 14 kDa and the presence of six conserved cysteine residues at characteristic positions (six-cysteine motif). OBPs of the lipocalin family have also been described in higher vertebrates but despite their common name with their insect counterparts, both families do not share any similarity at the sequence and at the structural levels suggesting convergent evolution in both lineages (Pelosi, P., 1994; Tegoni, M. *et al.*, 2000). With the growing number of OBP reports in other insect orders, it became apparent that all criteria could not always be met and OBP membership relied primarily on circumstantial functional evidences in the face of relaxed sequence homology. The identification of multiple OBPs in several insect species and the description of a new subfamily of OBPs called general odorant-binding proteins (GOBPs) in Lepidoptera provided good support that OBPs were part of a multigene family with an intrinsic role in perireception (Vogt, R. G. *et al.*, 1989; 1991; Robertson, H. M. *et al.*, 1999). This notion would be strengthened by the identification of *Obp* genes in a wide range of insect species including Coleoptera (Nikonov, A. A. *et al.*, 2002), Hymenoptera (Briand, L. *et al.*, 2001), Diptera (Kim, M. S. *et al.*, 1998), Orthoptera (Picone, D. *et al.*, 2001), Dictyoptera (Riviere, S. *et al.*, 2003), and Heteroptera (Vogt, R. G. *et al.*, 1999). Approximately 20 years after the initial *Apol*PBP characterization, the availability of *D. melanogaster* and *An. gambiae* genomes resulted in an explosion of putative *Obps* when over 50 genes were described based on similar structural features but not necessarily based on similar functional properties (Hekmat-Scafe, D. S. *et al.*, 2002; Xu, P. X. *et al.*, 2003).

4.33.3.1.1 Comparative evolutionary genomics

The genomes of *D. melanogaster* and *An. gambiae* contain 49 and 57 potential *Obp* genes, respectively (Hekmat-Scafe, D. S. *et al.*, 2002; Xu, P. X. *et al.*, 2003).

Within this classification, the six-cysteine motif, as a structural standard, has not always been completely adhered to, and *Obp* classification has relied on more broadly based sequence homology strategies using different variations of the BLAST algorithm (Altschul, S. F. *et al.*, 1990). Alignment of deduced OBP sequences indicates a diverse family of proteins with low-average amino acid identity within a given species of approximately 15–20% range (from 5% to 100% and from 9.2% to 62.6% range in *An. gambiae* and *D. melanogaster*, respectively) (Galindo, K. and Smith, D. P., 2001). OBP protein size typically ranges from 14 to 35 kDa and most have a potential peptide signal at their N-terminus. Moreover, this heterogeneous group encompasses several variations of the typical *Obp* gene group. In *D. melanogaster*, the *Obp* gene family includes 29 classic, 14 plus-C, and 6 minus-C genes. In *An. gambiae*, there are 29 typical, 12 plus-C, and 16 atypical *Obp* genes (see description below). The classic *Obp* genes are predicted to encode short 14 kDa proteins with six stereotypically placed cysteine residues and represent the archetype to which all other *Obp* types are compared. Most *Obp* genes include up to three introns that are distributed between the nine conserved positions shown in Figure 2. Generally, the first intron is located immediately downstream of the DNA encoding the putative peptide signal, which is presumably necessary for the extracellular expression of the mature protein. In the majority of cases (>80%), these introns occur between codons (phase 0) (Hekmat-Scafe, D. S. *et al.*, 2002). Classical *Obps* are predicted to encode six α-helical proteins and to form a globular compact structure reinforced by the presence of three disulfide bridges as shown by the structural studies on the pheromone-binding protein (PBP) of *Bombyx mori* (*Bmor*PBP) (Sandler, B. H. *et al.*, 2000).

Although these genes are distributed throughout the genome, most of them are cytogenetically clustered (Figure 3). In the case of *D. melanogaster*, more than half of the *Obp* genes (57%) are located on chromosome *2R*, where 14 *Obp* genes are clustered within a 825-kb stretch that also encompasses OR gene *Or56a* (Galindo, K. and Smith, D. P., 2001; Graham, L. A. and Davies, P. L., 2002; Hekmat-Scafe, D. S. *et al.*, 2002). In contrast, chromosome 2L of *D. melanogaster* carries only one *Obp* gene. *An. gambiae Obp* gene clusters are more dispersed and characteristically smaller. In both species these gene clusters tend to be localized at the tips of chromosome and rather than being organized in tandem arrays, typically occur in forward and backward orientations, suggesting that this family is rapidly evolving via multiple duplication and rearrangement events.

Many sequence analyses have been done on OBPs mainly to understand the structural relationships between members of this highly divergent gene family. All OBPs described to date have been restricted to insects within the Neoptera superorder. They include Lepidoptera, Diptera, Hymenoptera, Coleoptera (holometabolous insects), and one Hemiptera (hemimetabolous insects). Phylogenetic analyses have shown that three subfamilies seem to be monophyletic (i.e., subgroups of OBPs belonging to one insect lineage). The PBP/GOBP subfamily is restricted to the Lepidoptera (Figure 4). Their

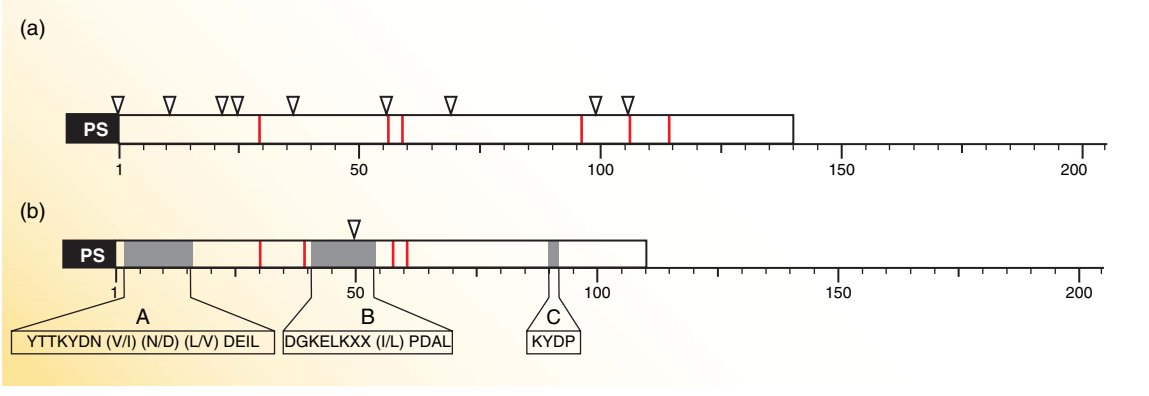


Figure 2 Gene structure and protein motifs of the *Obp* and *Csp* gene families. Genomic locations of *Or* (blue), *Csps* (yellow), and *Obps* (red) are listed on each chromosome of (a) *An. gambiae* and (b) *D. melanogaster* (data from Hill, C. A. *et al.*, 2002; Robertson, H. M. *et al.*, 2003; Xu, P. X. *et al.*, 2003; Hekmat-Scafe, D. S. *et al.*, 2002; Galindo, K. and Smith, D. P., 2001; Zhou, J. J. *et al.*, 2004; Biessmann, H. *et al.*, 2005; Wanner, K. W. *et al.*, 2004). (c) Positions in the entire *C. elegans* genome of all analyzed members of chemoreceptor (*Cr*) families. Adapted from Robertson, H. M. and Thomas, J. H. The putative chemoreceptor families of *C. elegans* (January 6, 2006), WormBook, ed. The *C. elegans* Research Community, WormBook, doi/10.1895/wormbook.1.66.1, http://www.wormbook.org. Picture of the *C. elegans* was kindly provided by Z. Altun and D. Hall.

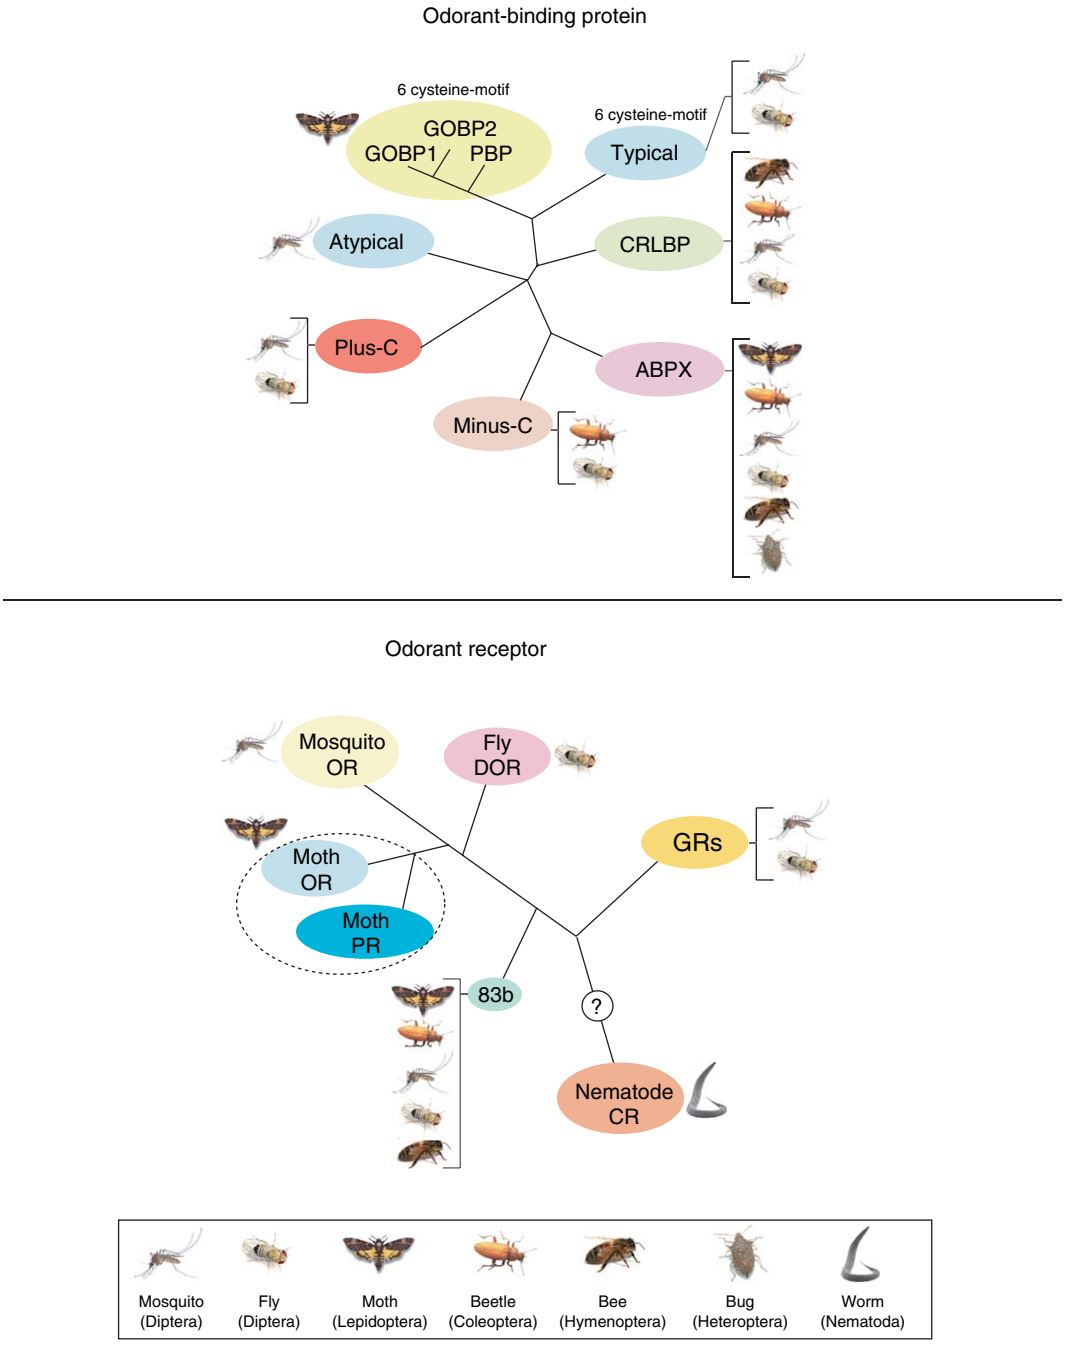

Figure 4 Stylized representation of the phylogenetic relationships of the insect *Obp* and invertebrate *Or* gene families. While the phylogenetic trees of odorant-binding proteins (OBPs) and odorant receptors (ORs) proteins are meant to display the various subfamilies (colored ovals), the phylogenetic relationships represented here do not represent true phylogenetic distances.

absence from other insect lineages suggests that this family arose within the Lepidoptera. This subfamily is subdivided into three subgroups based on sequence homology: PBP, GOBP1, and GOBP2 groups. PBPs are highly divergent (20–95% amino acid identity) while within one GOBP group the percentage of amino acid increases to 90%. In the case of the *Manduca sexta* PBP1–GOBP2 cluster, gene duplication

is one of the mechanisms that is likely to be responsible for generating molecular diversity (Vogt, R. G. *et al.*, 2002). Here, it was shown that both genes are approximately 2 kb apart, share identical exon-intron boundaries and are oriented in the same direction. As in the case of *D. melanogaster*, evolutionarily related genes seemingly share similar genomic features such as close cytogenetic position (gene clustering) and identical exon–intron boundaries. Although, it is important to know that these common features do not necessarily mean similar expression pattern and/or functional relationships.

Plus-C *Obps* have been identified only in Dipterans and thus must have arisen prior to the mosquito/fly divergence ~250 million years ago (mya). In Diptera, there are approximately a dozen Plus-C subfamily members per genome that are distributed in a few clusters (Zhou, J. J. *et al.*, 2004). The Plus-C group contains several divergent features from the classical *Obps*. Most notably a unique exon/intron usage not present in other *Obp* subgroups. In addition, Plus-C proteins average length 250 AA in length including 12 cysteine residues. Eleven Plus-C *Obps* have been described in *Drosophila pseudoobscura* (Zhou, J. J. *et al.*, 2004) and each of them has a strong counterpart in *D. melanogaster* as suggested by phylogenetic analysis. Significantly, the clustering pattern and synteny between these two Drosophilids is also extremely conserved for animals that diverged approximately 25–55 mya (Richards, S. *et al.*, 2005), and this may be indicative of similar function across all Drosophilids. This genomic organization suggests that many of these genes arose via duplication and evolved rapidly. There is only partial sequence similarity between Plus-C OBPs in these two species (overall 20%), and the majority has been shown to be expressed in the antenna and possess a peptide signal (Zhou, J. J. *et al.*, 2004; Biessmann, H. *et al.*, 2005).

Minus-C *Obp* genes have also been identified in several insect orders including Diptera and Coleoptera (Figure 4). Most *D. melanogaster* Minus-C genes (four out of six) are clustered at the tip of chromosome 3R, exhibit very low sequence similarity (~20% amino acid identity), and lack two of the six canonical cysteine residues, usually C2 and C5. Interestingly, non-Diptera Minus-C *Obps* also lack cysteines C2 and C5. Among them, *Tenebrio molitor* B1, B2, and Thp12 are hemolymph proteins (Paesen, G. C. and Happ, G. M., 1995; Rothemund, S. *et al.*, 1999; Graham, L. A. and Davies, P. L., 2002) suggesting that their *Drosophila* homologs may also have nonolfactory functions. However, the other two *Drosophila* Minus-C proteins each contain all six cysteine residues, are expressed in the antennae (Galindo, K. and Smith, D. P., 2001) raising the possibility that olfactory function may be dependent upon the retention of a set of particular structural motifs.

Atypical *Obps* are more similar to the classic *Obp* genes but distinct from the plus-C class, and thus far have been found only in *An. gambiae* where 16 genes are predicted, and it is likely that this subfamily arose after the fly/mosquito divergence (Xu, P. X. *et al.*, 2003). Indeed homology searches have failed to identify atypical *Obps* in *Drosophila*. While atypical *Obps* display the six-cysteine hallmark of classic *Obps*, they display a characteristically elongated C-terminus containing up to seven additional cysteine residues located downstream of the six-cysteine motif. Furthermore, atypical *Obp* genes lack introns in their predicted coding regions. Two clusters of seven and three genes are located on chromosome X and 3L, respectively, with the remaining genes being scattered throughout the genome. As is typical for other *Obp* classes these genes share a low 20.2% amino acid identity (Hekmat-Scafe, D. S. *et al.*, 2002).

The antennal-binding protein family (ABPX) (Krieger, J. *et al.*, 1996) encompasses *Obps* from several insect orders (Figure 4). They were first identified in *B. mori* where they displayed little homology to the PBP/GOBP subfamily. To date, this subfamily includes several Drosophila and mosquito genes including olfactory-specific proteins E and F (*OS-E*, *OS-F*), *Ag-Obp1*, *Ag-Obp2*, *Ag-Obp3*, and *Ag-Obp17*, the *Lygus* antennal protein (LAP) (Vogt, R. G. *et al.*, 1999), several beetle *Obps* (Wojtasek, H. and Leal, W. S., 1999), and a single queen bee *Obp* (Danty, E. *et al.*, 1999). Lastly, a separate but related class of OBP-like proteins known as the chemical sense-related lipophilic ligand-binding proteins (CRLBP) were first identified in the contact chemoreceptor sensilla of the blowfly *Phormia regina* (Ozaki, M. *et al.*, 1995; Tsuchihara, K. *et al.*, 2005). Other CRLBP members have been identified in Coleoptera (Wojtasek, H. and Leal, W. S., 1999), Diptera, and in the honeybee *Apis mellifera* (Danty, E. *et al.*, 1999).

4.33.3.1.2 Functional genomics of Obps

Obps or *Obp*-like genes have been identified in vertebrates and insects. Although both OBP families are phylogenetically unrelated, both taxa have developed similar mechanisms at the perireceptor level to facilitate or to modulate the interaction between ORs and their ligands. It is therefore striking that no OBPs have been described in *C. elegans* suggesting that the nematode chemosensory system has evolved

without the requirement of *Obps* for its signal transduction pathway. This raises the possibility as to whether OBPs are required for olfactory functions in all cases. What is the evidence supporting such function for this gene family? And, do these proteins possess *bone fide* odorant-binding capabilities?

The assumption of their olfactory involvement was for more than 20 years circumstantial and relied on *in vitro* experiments that were rather difficult to interpret. Evidences largely drew from the differential pattern of *Obp* expression that was distinguished by high levels of antennal transcripts. Indeed, the central dogma of OBP expression studies consistently maintained that moth PBPs were preferentially expressed in male pheromone-sensitive trichoid sensilla whereas GOBPs were expressed in the general plant-volatile-sensitive basiconic sensilla of both sexes (Vogt, R. G. *et al.*, 1991). This situation changed when the expression of PBPs and GOBPs was reported in male and female adult moths and of GOBPs in larvae albeit with different expression patterns (Vogt, R. G. *et al.*, 2002). Furthermore, immunocytochemistry experiments were able to localize their exact expression to the sensillum lymph bathing the ORN (Steinbrecht, R. A., 1998).

The crystal structure of *B. mori* PBP and its natural bound ligand, bombykol, provided a structural model to investigate the nature of this molecular relationship and the potential consequences on OR activation by such a complex (Sandler, B. H. *et al.*, 2000). Five additional OBP structures have been resolved from different insect orders including *Dmel*-LUSH (Kruse, S. W. *et al.*, 2003), cockroach *Leucophaea maderae* PBP (Lartigue, A. *et al.*, 2003), the honeybee *A. mellifera* ASP1 (Lartigue, A. *et al.*, 2004), *A. polyphemus* PBP (Mohanty, S. *et al.*, 2004), and *An. gambiae* OBP1 (Wogulis, M. *et al.*, 2006). In all cases a similar potential of hydrogen (PH)-dependent mechanism seems likely to be responsible for the release of the ligand.

Definitive evidence for olfactory function was provided by the characterization of the only mutant defective for OBP expression: the *Drosophila OBP76a* mutant, also referred to as *lush* (Figure 5). *Lush* mutants display an abnormal attraction to toxic levels of ethanol (Kim, M. S. *et al.*, 1998) and a loss of sensitivity to the aggregation of pheromone 11-*cis*-vaccenyl acetate (VA) (Xu, P. *et al.*, 2005). These two compounds are detected by two different subsets of trichoid sensilla also corresponding to *lush* expression. Transgenic rescue and the introduction of LUSH protein into the recording pipette of VA-sensitive neuron in mutant flies were shown to restore the electrophysiological response to this compound. More importantly, using alternative putative carrier such as DmelOBP83a (OSF) or bovine serum albumin (BSA) did not restore the wild-type phenotype demonstrating that *lush* is specifically required for the transduction pathway of VA.

If *Obp* expression in olfactory sensilla can be used to infer olfactory function, then their expression in nonolfactory tissues requires the assumption of alternative functions. In *Drosophila*, where Galindo K. and Smith D. P. (2001) studied the expression pattern of over 30 *Obps* by LacZ promoter fusions, four classes were distinguished based on their expression pattern: olfactory, taste, olfactory and taste, and nonchemosensory. The last class includes the Drosophila *Obp19d* (*pbprp2*) whose expression is quite ubiquitous and is expressed in olfactory sensilla coeloconic, in various taste organs, and in the epidermis (Park, S. K. *et al.*, 2000; Galindo, K. and Smith, D. P., 2001; Shanbhag, S. R. *et al.*, 2001). Accordingly, a scavenger function has been proposed for this class of *Obps* (Park, S. K. *et al.*, 2000; Shanbhag, S. R. *et al.*, 2001).

4.33.3.2 Insect Chemosensory Proteins

The *Csp* gene family also encodes a group of small, water-soluble proteins presumed to act as carriers for small hydrophobic compounds. CSPs are smaller (~110 AA) than OBPs and have four cysteine residues whose positions are also strictly conserved. The crystal structure of the noctuid *Mamestra brassicae* CSP-A6 has six α-helices surrounding a hydrophobic binding pocket and two disulfide bridges in a folding pattern different from that of OBPs (Lartigue, A. *et al.*, 2002). The first member of this family (A10) was identified in *D. melanogaster* and due to its antennal expression was denoted as olfactory-specific D or OS-D (McKenna, M. P. *et al.*, 1994). Subsequent members of this family were referred as OS-D like, pherokine (Phk), or sensory appendage protein (SAP) based on their expression in various sensory structures. CSPs have been identified in many insect orders including Hymenoptera, Diptera, Lepidoptera, Dictyoptera, Orthoptera, Hemiptera, and Phasmatodea. The hallmark of the encoded protein family includes four invariant cysteine residues at conserved positions $CX_6CX_{18}CX_2$. There are two classes of CSPs. The first class contains three conserved amino acid motifs: an N-terminal motif A [YTTKYDN(V/I)(N/D)(L/V)DEIL], a central motif B [DGKELKXX(I/L)PDAL], and a C-terminal motif C [KYDP] (Figure 2). Proteins that diverge from this pattern belong

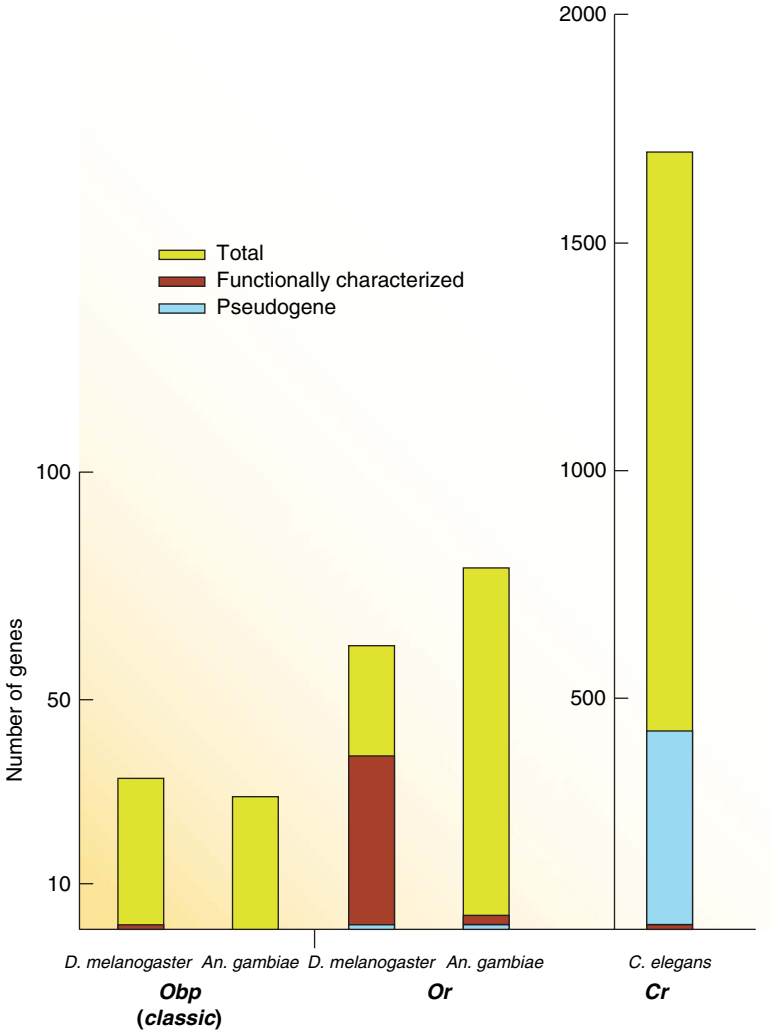

Figure 5 Known gene families in insects and nematodes. (a) *Or* and *Obp* gene repertoires in *Anopheles gambiae*, *Drosophila melanogaster*, and *Caenorhabditis elegans*. Green, total number of genes; blue, number of pseudogenes; and brown, functionally characterized genes.

to a second class. The conservation of sequence, structural motifs, intron site, and genomic clustering in the insect Neoptera infraclass (insect with wing folding) suggest an ancient origin predating the Neoptera–Paleoptera divergence. See Wanner K. W. *et al.* (2004) for a detailed review.

4.33.3.2.1 Genomic organization and gene structure of Csps

How do *Csp* repertoires compare to *Obp* repertoires? The genome of *D. melanogaster*, *D. pseudoobscura*, *A. mellifera*, and *An. gambiae* have 4, 4, 6, and 6 *Csp* genes, respectively (Wanner, K. W. *et al.*, 2004). Generally, CSPs are more conserved than OBPs with an average of 50% amino acid identity within and between species and typically have 0 or 1 introns (Figure 2). When present, the intron splice site is strictly conserved one nucleotide past an invariant lysine residue (phase 1 intron). All *An. gambiae Csp* genes are clustered within a 120 kb stretch on chromosome 3R, while in *Drosophila*, Os-D is isolated on chromosome 3L and three other *Csps* are located within ~1 Mb of each other on chromosome 2R. Synteny is highly conserved between *D. melanogaster* and *D. pseudoobscura*.

4.33.3.2.2 Functional genomics of Csps

The function of the *Csp* genes has been inferred exclusively based on indirect evidence such as expression patterns and structural studies. Contrary to *Obps*, *Csps*

are, for the most part, expressed in several chemosensory and nonchemosensory tissues. *In situ* hybridization and *in vitro* binding studies of the moth *M. brassicae Csp* (*MbraCsp*) genes and their encoded proteins correlate their expression to the antenna and proboscis tissues. CSPs were also found in the pheromone gland, which is lacking olfactory organs (Nagnan-Le Meillour, P. *et al.*, 2000; Jacquin-Joly, E. *et al.*, 2001). In locusts different subclasses of *Csps* are associated with different tissues including the gustatory sensilla chaetica, which are distributed throughout the body and in the subcuticular space between the antennal epithelium and the cuticle (Angeli, S. *et al.*, 1999; Jin, X. *et al.*, 2005). Interestingly, in locust sensilla chaetica, CSPs are restricted to the noninnervated sensillum lymph compartment suggesting that they act outside of chemosensory processes.

The Drosophila genome (Figure 3) contains four *Csp* genes and encapsulates the multifunctional reality of the *Csp* gene family. *DmelOS-D/pherokine-1* expression is associated with the coeloconic sensilla on the antenna. Pherokine-2 (Phk-2 also known as ejaculatory bulb protein III PEBIII) is expressed solely in male ejaculatory bulbs, which contains VA. During copulation, VA is transferred to the female and has an antiaphrodisiac effect on male courtship (Brieger, G. and Butterworth, F. M., 1970). Interestingly, Phk-2 shares 50% identity with *M. brassicae* CSP (MbraOBP2) that binds VA *in vitro* (Bohbot, J. *et al.*, 1998). Phk-2 is also 53% identical to the *Periplaneta americana* protein p10, whose expression is significantly enhanced during leg regeneration of juvenile cockroaches and is also expressed in other tissues of juveniles and adults (antenna and head) (Kitabayashi, A. N. *et al.*, 1998). Both Phk-2 and Phk-3 expression are enhanced following viral and bacterial infection, respectively (Sabatier, L. *et al.*, 2003). The authors suggested that pherokines, including OSD, present a defense mechanism against microorganism entry regions such as the sensillum where the lymph and the environment are in contact.

In conclusion, the ubiquitous expression pattern of CSPs, their specific mode of regulation, and broad ligand recognition capabilities (Nagnan-Le Meillour, P. *et al.*, 2000; Jacquin-Joly, E. *et al.*, 2001; Lartigue, A. *et al.*, 2002) are consistent with the suggestion that this gene family is involved in the transport of hydrophobic ligands in various physiological pathways.

4.33.3.3 Odorant Receptors

The most numerous and well-studied chemosensory genes are the ORs, followed distantly by the gustatory receptors (GRs). While the ORs are a clear subclass of chemoreceptors in insects (Figure 4) (Hill, C. A. *et al.*, 2002; Robertson, H. M. *et al.*, 2003; Bohbot, J., *et al.*, 2007; Nene, V., *et al.*, 2007) the distinction between olfaction and gustation, and thus ORs and GRs, is less clear in the nematode *C. elegans* (Bergamasco, C. and Bazzicalupo, P., 2006). For the purpose of this chapter, the *C. elegans* chemosensory receptors will be considered as olfactory genes, although their relationship to insect ORs is ambiguous at best (Figure 4). As a class, ORs dominate the invertebrate GPCR landscape, accounting for one-quarter to one-half of all GPCRs in insect genomes (Hill, C. A. *et al.*, 2002; Bohbot *et al.*, in preparation) and perhaps more than half of all GPCRs in *C. elegans* (Ono, Y. *et al.*, 2005; Robertson, H. M. and Thomas, J. H., 2006).

As a whole, the invertebrate ORs are an extremely divergent family of genes, often displaying very low similarity among members within the same species and with few apparent orthologues between species (Robertson, H. M. *et al.*, 2003; Ache, B. W. and Young, J. W., 2005; Robertson, H. M. and Thomas, J. H., 2006). While the vertebrate ORs are also characteristically divergent they show much more similarity than their invertebrate counterparts (Mombaerts, P., 2004). Furthermore, vertebrate ORs lack introns while the invertebrate *Or* genes contain introns, making their annotations considerably less straightforward. Intron gain and loss in invertebrate ORs is evident and has been used as one indicator of their phylogenetic relationships (Robertson, H. M., 1998; 2000; Robertson, H. M. *et al.*, 2003). As is the case for vertebrate *Or* genes, invertebrate OR loci are often clustered, ranging from just a few tandem genes in *D. melanogaster* (Robertson, H. M. *et al.*, 2003) to an enormous proliferation of loci on *C. elegans* chromosome V (Figure 3) (Robertson, H. M. and Thomas, J. H., 2006). In many cases, tandem or clustered groups of genes are paralogous, representing recent duplications of receptors. Another distinction between the vertebrate and invertebrate OR families is in the number of apparent pseudogenes. Vertebrate genomes contain as many as 50% *Or* pseudogenes (Mombaerts, P., 2004; Ache, B. W. and Young, J. M., 2005), and as many as one-third of the chemoreceptors have been reported as pseudogenes in the N2 strain of *C. elegans* (Robertson, H. M., 1998; 2000; Robertson, H. M. and Thomas, J. H., 2006). In contrast, insects families retain very few *Or* pseudogenes (Hill, C. A. *et al.*, 2002; Robertson, H. M. *et al.*, 2003; Ache, B. W. and Young, J. M., 2005; Bohbot *et al.*, in preparation). Together with the widespread occurrence of single nucleotide polymorphisms in the

insect and the nematode ORs (Hill, C. A. *et al.*, 2002; Robertson, H. M. and Thomas, J. H., 2006; Bohbot *et al.*, in preparation), their overall divergence, intron flux, and duplications suggest that the invertebrate ORs are very rapidly evolving gene families. This rapid evolution may have arisen out of the need for adapting to changing environments, mating specificity, and otherwise differing life histories of divergent species (Robertson, H. M. *et al.*, 2003; Robertson, H. M. and Thomas, J. H., 2006).

4.33.3.3.1 Insect odorant receptors

The identification of the first vertebrate ORs (Buck, L. and Axel, R., 1991) led to a major effort by several groups interested in identifying insect ORs. Nearly a decade later, the release of the *D. melanogaster* genome facilitated the identification of a family of ORs from *D. melanogaster* (Clyne, P. J. *et al.*, 1999; Gao, Q. and Chess, A., 1999; Vosshall, L. B. *et al.*, 1999). Since then a significant body of work has been put forth describing insect *Or* genes, their patterns of expression, functions, and implications for odor coding (Robertson, H. M. *et al.*, 2003; Hallem, E. *et al.*, 2004a; Hallem, E. A. *et al.*, 2004b; Jacquin-Joly, E. and Merlin, C., 2004; Ache, B. W. and Young, J. M., 2005; Dahanukar, A. *et al.*, 2005; Jefferis, G. S. X. E., 2005; Rutzler, M. and Zwiebel, L., 2005). The completion of the genome of the malaria mosquito, *An. gambiae* (Holt, R. A. *et al.*, 2002), led to the description of a second complete insect OR gene family and to the comparison of *An. gambiae* and *D. melanogaster* OR repertoires (Fox, A. N. *et al.*, 2001; Hill, C. A. *et al.*, 2002). Multiple ORs have now been identified in species from at least four other insect orders including Diptera, Lepidoptera, Hymenoptera (Krieger, J. *et al.*, 2003), and Coleoptera (reviewed in Hallem, E. A. *et al.*, 2006). Furthermore, a single OR is highly conserved across insect orders, widely coexpressed with other ORs, and required for their function (Krieger, J. *et al.*, 2003; Larsson, M. C. *et al.*, 2004; Pitts, R. J. *et al.*, 2004; Jones, W. D. *et al.*, 2005; Xia, Y. and Zwiebel, L. J., 2006) (Figure 4). It is apparent that with several insect genome projects nearly completed or about to be initiated, the future of comparative genomics is certain to yield new and exciting information.

4.33.3.3.1.(i) Drosophila odorant receptors When homology-based cloning efforts repeatedly failed, the first wave of insect OR identification was the direct result of a novel approach for bioinformatics-based searches of the *D. melanogaster* genome project (Clyne, P. J. *et al.*, 1999). The complete set of *D. melanogaster* 60 *Or* genes (*DOrs*) encoding 62 Drosophila olfactory receptor (DOR) peptides in the Drosophila genome (Robertson, H. M. *et al.*, 2003) followed soon after (Vosshall, L. B. *et al.*, 1999; Vosshall, L. B., 2000), launching a revolution in insect olfactory research, most of which will be reviewed in other chapters in this volume. DORs are a very divergent family, most sharing less than 20% identity, with limited subfamilies having >40% identity (Vosshall, L. B., 2000). In contrast, their vertebrate counterparts generally display a much higher level of similarity of at least 40% among mouse ORs, for example (Zhang, X. and Firestein, S., 2002).

DOrs display interesting gene structures, some of which are conserved among animal ORs. For example, *DOrs* are dispersed as single genes throughout the Drosophila genome (Figure 3) (Robertson, H. M. *et al.*, 2003). Those genes that are grouped occur as doublets or triplets and generally are most similar to one another, suggesting that they represent gene duplication events (Robertson, H. M. *et al.*, 2003). The *DOr19a* and *DOr19b* genes, which are tightly linked, inverted relative to one another, and whose peptide translations are >90% identical, are an example of one such recent duplication (Robertson, H. M. *et al.*, 2003). In contrast to the widely dispersed locations of *DOrs*, *Ors* from other insects and *C. elegans* are often found in moderate to large clusters (Figure 3) (Hill, C. A. *et al.*, 2002; Robertson, H. M. and Thomas, J. H., 2006), and significant clustering is also common for vertebrate *Or* genes (Mombaerts, P., 2004). Two *DOrs* apparently produce multiple proteins by alternate splicing (Robertson, H. M. *et al.*, 2003). *DOr46a* and *DOr69a* each produce a second 'b' peptide, *DOr46a* by the splicing of a single C-terminal exon encoding the seventh transmembrane (TM) and *DOr69a* by the splicing of two C-terminal exons encoding the sixth and seventh TMs, to unique N-terminal exons (Robertson, H. M. *et al.*, 2003). Alternative splicing is a feature common to insect GRs (Clyne, P. J. *et al.*, 2000; Hill, C. A. *et al.*, 2002) and has been documented at low frequency in vertebrate ORs (Young, J. *et al.*, 2003), which lack introns (Mombaerts, P., 2004). In contrast, *DOrs* contain between one and nine introns with typically four of the C-terminal introns likely to be ancestral in the *DOr* lineage, two of which are shared with *DGrs*, reflecting their common derivation (Figure 6) (Robertson, H. M. *et al.*, 2003).

DOrs are expressed in adult antennae, maxillary palps, and in the dorsal organ of larvae (Clyne, P. J. *et al.*, 1999; Gao, Q. and Chess, A., 1999; Vosshall, L. B.

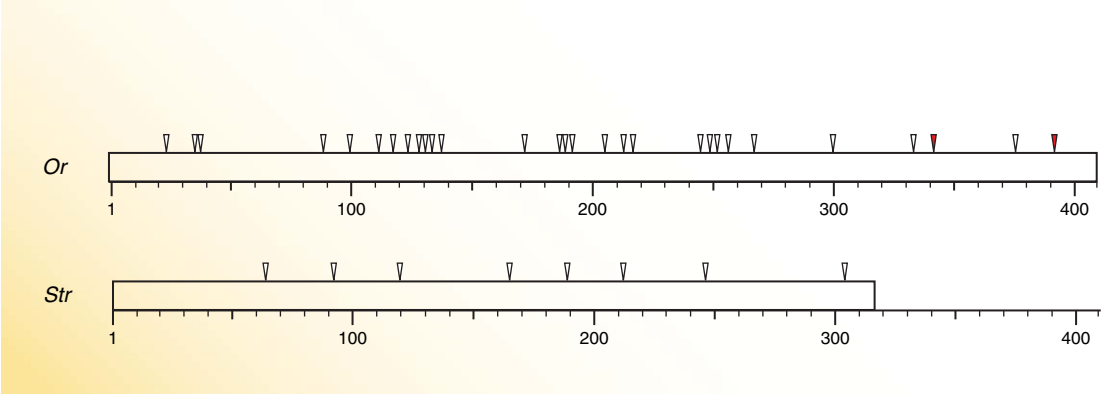

Figure 6 Locations of introns in the *Or*/*Str* genes in *Drosophila* and *Caenorhabditis elegans*. The intron locations (arrowheads) are shown relative to a scale of the average receptor size in amino acids. Red introns indicate ancient introns. Data from Robertson H. M. *et al.* (2003) and Robertson H. M. (1998).

et al., 1999; Vosshall, L. B. *et al.*, 2000). Their expression is limited to specific sensillar types in stereotypic regions of the antennae, and their patterns and projections are conserved from individual to individual (Vosshall, L. B. *et al.*, 2000). While generally little is known about the regulation of *DOr* expression, one important example stands out. The *D. melanogaster* mutant, *abnormal chemosensory jump 6* (*acj6*), was isolated based on its reduced jumping response to odor stimuli (McKenna, M. P. *et al.*, 1989), as well as defects of olfactory physiology (Ayer, R. K. and Carlson, J., 1991). A*cj6* encodes a Pitl Octl Unc-86 (POU) domain transcription factor that is expressed in ORNs and directly effects the expression of several *DOrs* (Clyne, P. J. *et al.*, 1999). The regulation of *Or* expression level and location is likely to play a significant role in establishing olfactory sensitivity. Future studies will undoubtedly reveal the *cis*-acting DNA elements and *trans*-acting protein factors that are involved in *Or* gene regulation and that whether these elements are conserved among invertebrates.

Functional studies of invertebrate ORs will be more thoroughly discussed in other chapters in this volume. But as they relate to receptor gene similarities the following points are worth mentioning. More than half of the *DOrs* have been functionally characterized (Figure 5) (Dobritsa, A. A. *et al.*, 2003; Hallem, E. *et al.*, 2004a; Goldman, A. L. *et al.*, 2005; Kreher, S. A. *et al.*, 2005) and most receptors appear broadly tuned to many different odors across different molecular classes (Hallem, E. *et al.*, 2004a). Surprisingly, phylogenetically related receptors are not necessarily tuned to related compounds (Hallem, E. *et al.*, 2004a). For example, DOR9a and DOR47a, while forming a monophyletic clade in a phylogenetic analysis, are tuned to multiple, nonoverlapping odorants (Hallem, E. *et al.*, 2004a). It is too early to comment as to whether this complex relationship between ligand specificity and OR homology may prove to be a general trend for invertebrate ORs.

4.33.3.3.1.(ii) Anopheles odorant receptors Soon after the identification of *DOrs*, candidate *Or* genes were identified with homology-based approaches from *An. gambiae* (*AgGPRors*) (Fox, A. N. *et al.*, 2001; 2002). The completion of the *An. gambiae* genome sequence (Holt, R. A. *et al.*, 2002) facilitated the characterization of 79 *AgGPRors*, representing the second complete set of insect *Ors*. Like their *DOr* counterparts, the *AgGPRors* are a very diverse group of genes, the vast majority share less than 20% identity at the amino acid level, although 28 pairwise identities are higher than 70% (Fox, A. N. *et al.*, 2001; Fox, A. N. *et al.*, 2002; Hill, C. A. *et al.*, 2002). Indeed, several AgGPRors are so similar (>90% identity for proteins encoded by *AgGPRors75,76,78* and *AgGPRors77,79*) as to suggest that they are either very recent duplications or alternatively alleles of the same gene that has been erroneously ascribed separate loci in the annotation of a mixed haplotype genome.

Phylogenetic comparison of the *DmOrs* and *AgGPRors* illustrates the extreme divergence between insect OR that has become the hallmark of these gene families. Most groupings with high bootstrap support are made up of receptors from the same species while only a few highly divergent ORs from both species are grouped together (Hill, C. A. *et al.*, 2002).

AgGPROR7 is the sequence as well as the functional orthologue of DOR83b and represents a unique OR subfamily (see below), the two sharing a remarkable 78% identity and ~90% similarity (Pitts, R. J. *et al.*, 2004). The next best examples are AgGPRor2 and DmOr43a, which share just 36% identity and ~70% similarity (Fox, A. N. *et al.*, 2001; Hill, C. A. *et al.*, 2002). Interestingly, AgGPRor2 and DmOr43a do not appear to share odorant ligand specificity (Storkuhl, K. F. and Kettler, R., 2001; Wetzel, C. H. *et al.*, 2001; Hallem, E. *et al.*, 2004a; Hallem, E. A. *et al.*, 2004b).

The *AgGPRors* are dispersed on all three chromosomes, although there are several tightly linked loci with as many as nine genes (Figure 3) (Hill, C. A. *et al.*, 2002). In each case the clustered genes are very similar to one another and are generally transcribed in the same direction, indicating that they have likely arisen as a result of multiple duplication events (Hill, C. A. *et al.*, 2002). Like the *DOrs*, all *AgGPRors* contain introns (Fox, A. N. *et al.*, 2001; 2002; Hill, C. A. *et al.*, 2002; Pitts, R. J. *et al.*, 2004), and many *AgGPRors* share one or more 3′ ancestral introns of *DOrs*, supporting a common, distant derivation (Pitts, R. J. *et al.*, 2004; Zwiebel lab, unpublished data).

To date, two *AgGPRors* have been functionally characterized (Hallem, E. A. *et al.*, 2004b). One of those genes, *AgGPRor1*, displays enhanced female expression that is downregulated after blood feeding (Fox, A. N. *et al.*, 2001) and is sensitive to a component of human sweat (Hallem, E. A. *et al.*, 2004b). This is an intriguing finding and may ultimately lead to the design of strategies to interfere in Anopheles, if not mosquito-specific, in the olfactory-driven behaviors, such as host-seeking, in these disease vectors.

4.33.3.3.1.(iii) Lepidopteran odorant receptors

The first Lepidopteran candidate *Ors* (*HR1–HR9*) was identified and cloned from the tobacco budworm moth, *Heliothis virescens*, as a result of screening a proprietary genome project (Krieger, J. *et al.*, 2002). Twelve more *Ors* were subsequently identified, many of which have been classified as candidate pheromone receptors (PRs) and are discussed below (Krieger, J. *et al.*, 2004). While this analysis is presumed to represent only a subset of the OR repertoire from *H. virescens*, we can make several inferences albeit limited in their scope from this work. As noted for other insect ORs, the putative HRs have a canonical seven-TM structure, but are nevertheless a very divergent group of genes whose conceptual translations share very low sequence identity with *D. melanogaster* ORs and GRs (Krieger, J. *et al.*, 2002). Intraspecifically, HRs share low identity among the nonpheromone receptor candidates, generally 8–15%, the highest identities being 52% and 34% between HR7 and HR9 (Krieger, J. *et al.*, 2002) and HR7 and HR12, respectively (Krieger, J. *et al.*, 2004). Although genomic DNA fragments were identified from the *H. virescens* genome, no data regarding introns or map positions were presented (Krieger, J. *et al.*, 2002), and the fact that the *H. virescens* genome is a nonpublic resource has made genomics comparisons with other insect ORs impossible at present. All candidate receptors examined by RT-PCR were expressed in antennae with a subset expressed in other chemosensory tissues (Krieger, J. *et al.*, 2002; 2004). *In situ* hybridization revealed that two receptors, *HR6* and *HR8*, are expressed in distinct groups of antennal neurons (Krieger, J. *et al.*, 2002). Interestingly, it has been suggested that a subset of the identified *H. virescens ORs* might, in fact, encode functional GRs. Specifically, HRs1, 4, and 5 are expressed in tissues with potential gustatory function (Krieger, J. *et al.*, 2002) and form a monophyletic clade distinct from other HRs that shares their most significant cross-species similarity with *D. melanogaster* GRs (Krieger, J. *et al.*, 2004).

Eleven candidate PRs have now been identified from two moth species: six from *H. virescens* (Krieger, J. *et al.*, 2004; 2005) and five from the silkmoth, *B. mori* (Sakurai, T. *et al.*, 2004; Krieger, J. *et al.*, 2005; Nakagawa, T. *et al.*, 2005). Currently little is known about the genomics of these receptors beyond their coding sequences, peptide alignments, and phylogenies; accordingly, any speculation as to potential paralogy and orthology among these receptors must therefore await the completion of a more extended set of characterizations. Only the genomic structure of *BmOr-1* has been presented (Sakurai, T. *et al.*, 2004). The PR conceptual translations have low sequence similarity to ORs from other insect species and they form their own monophyletic clade within the limited moth receptor family (Krieger, J. *et al.*, 2004; Sakurai, T. *et al.*, 2004; Krieger, J. *et al.*, 2005). Their similarity to one another ranges from 35% to 70% identity within a species to greater than 40% identity between BmOR-3 and HRs 4, 11, 14, 15, and 16 (Krieger, J. *et al.*, 2005). The PRs are also longer, on average, than other insect ORs averaging 430 AA in *H. virescens* and 425 AA in *B. mori* (Krieger, J. *et al.*, 2005) as compared to an average of ~400 AA for *D. melanogaster* and *An. gambiae* ORs, respectively (Hill, C. A. *et al.*, 2002; Robertson, H. M. *et al.*, 2003).

A limited set of expression analyses and functional characterizations have been carried out for PRs. The expression of five of the six candidate *H. virescens* PRs and four of the five candidate *B. mori* PRs are either enhanced in or specific to male antennae, which is consistent with a putative role in pheromone sensing (Krieger, J. *et al.*, 2004; Sakurai, T. *et al.*, 2004; Krieger, *et al.*, 2005; Nakagawa, T. *et al.*, 2005; Gohl, T. and Krieger, J. R., 2006). Furthermore, an antibody against HR13 labels dendrites in the sensilla trichodea type 1, which are found only on male antennae and most of which are sensitive to the major component of the *H. virescens* female pheromone (Gohl, T. and Krieger, J. R., 2006). The silkmoth receptor BmOR-1 detects bombykol, the sole female sex pheromone, as shown by ectopic expression in female antennae, as well as heterologous expression in *Xenopus laevis* oocytes (Sakurai, T. *et al.*, 2004; Nakagawa, T. *et al.*, 2005). In these latter studies, while BmOR-1 alone induced a significant response to bombykol in oocytes, coexpression of the 83b subfamily member BmOR-2 greatly increased both the fraction of responsive oocytes and the magnitude of the individual responses (Nakagawa, T. *et al.*, 2005) leading to the suggestion, subsequently verified by *in situ* hybridization, that *BmOr-1* and *BmOr-3* neurons coexpress *BmOr2* (Nakagawa, T. *et al.*, 2005). In contrast, another study also used *in situ* hybridization to localize these receptors and drew the opposite conclusion, stating that neither *BmOr-1* nor *BmOr-3* colocalize with *BmOr-2* (Krieger, J. *et al.*, 2005). This striking paradox must await further investigation for its resolution and will undoubtedly be important, given the implication that 83b subfamily members may not be required for pheromone sensing in insects, but instead function only in general odorant perception.

4.33.3.3.1.(iv) DOr83b family From its initial identification and subsequent expression analysis, *DOr83b* gene was singled out as a potentially extraordinary OR (Vosshall, L. B. *et al.*, 2000). It is much longer than the average DOR, having an extended loop between the fourth and fifth putative transmembrane regions and, more strikingly, is expressed in nearly all antennae and maxillary palp neurons in *D. melanogaster* (Vosshall, L. B. *et al.*, 2000). The subsequent identification of *AgGPRor7* in *An. gambiae*, *AaGPRor7* in *Ae. Aegypti*, and *HR2* in *H. virescens* demonstrated that *DOr83b* is also extremely well conserved in other insects and represents an important receptor subfamily (Krieger, J. *et al.*, 2002; Melo, A. C. *et al.*, 2004; Pitts, R. J. *et al.*, 2004). In addition, conserved intron position between *DOr83b* and *AgGPRor7* as well as microsynteny with respect to neighboring genome regions also suggested true orthology, the first of its kind among insect ORs (Hill, C. A. *et al.*, 2002). Krieger J. *et al.* (2003) identified member genes from species representing multiple insect orders including Lepidoptera (*B. mori* and *Antheraea pernyi*), Diptera (*Calliphora erythrocephala*), Hymenoptera (*A. mellifera*) and Coleoptera (*T. molitor*), demonstrating the broad conservation of the 83b family.

The *DOr83b* subgroup is unique to insects and forms an ancestral monophyletic clade within the larger insect OR family, which interestingly is more similar than other ORs to GRs (Figure 4) (Robertson, H. M. *et al.*, 2003). The exceptional degree of sequence conservation and expression characteristics raised the obvious hypothesis that the *DOr83b* family might represent a nonconventional OR subfamily that is crucial to insect olfactory signal transduction (Vosshall, L. B., 2000). Indeed, several studies have since demonstrated its functional significance in olfaction. Initially, *DOr83b* knockdowns carried out in *D. melanogaster* using either reverse genetics or RNA interference (Larsson, M. C. *et al.*, 2004; Neuhaus, E. M. *et al.*, 2005) revealed an absolute requirement for *DOr83b* in normal olfactory responses. Furthermore, DOR83b was shown necessary and sufficient for the proper localization and retention of other conventional DOrs to the dendritic membrane (Larsson, M. C. *et al.*, 2004; Benton, R. *et al.*, 2006). Testing this hypothesis even further, transgenic expression of *DOr83b* orthologues from three different insect species in the antennae of *DOr83b*-mutant flies restored odorant sensitivity as well as the correct localization of conventional *DOrs* to ORN dendrites, providing direct evidence of their functional conservation (Jones, W. D. *et al.*, 2005). While heterologous expression studies revealed that members of the DOr83b family dimerize with conventional ORs and thereby enhance odorant response sensitivity (Wetzel, C. H. *et al.*, 2001; Sakurai, T. *et al.*, 2004; Neuhaus, E. M. *et al.*, 2005), DOR83b does not independently confer odorant sensitivity (Dobritsa, A. A. *et al.*, 2003; Benton, R. *et al.*, 2006). Lastly, recent studies suggest that DOr83b and other DOrs may have an unexpectedly inverted conformation in the dendritic membrane, with their N-termini located intracellularly and their C-termini located extracellularly (Benton, R. *et al.*, 2006). This potentially unique conformation, along with the apparent lack

of an 83b subfamily member of nonconventional ORs, further distinguishes the molecular components of insect olfactory signal transduction from its counterparts in both vertebrate and *C. elegans*. It will now be interesting to determine how far back in the hexapod lineage this receptor can be identified. We may indeed find that the principles of olfaction elucidated in insect model systems are conserved in older hexapods and even in other arthropod lineages, giving us insight into the evolution of olfaction in general, and potentially providing opportunities for broad-based control strategies that rely on olfaction for their implementation.

4.33.3.3.2 *Caenorhabditis elegans chemoreceptors*

Four years after the identification of vertebrate ORs (Buck, L. and Axel, R., 1991), the first candidate invertebrate chemoreceptors (*CeCrs*) were identified through bioinformatic methods in the soil nematode, *C. elegans* (Troemel, E. R. *et al.*, 1995). The expression of a subset of *CeCrs* was observed in chemosensitive neurons, consistent with the proposed chemoreceptor functions (Troemel, E. R. *et al.*, 1995). Since then, more than 20 gene families composed of nearly 1300 intact genes, and over 400 apparent pseudogenes, accounting for roughly 7% of all *C. elegans* genes, have been described (Robertson, H. M. and Thomas, J. H., 2006). By convention, *CeCr* gene family names usually begin with the initials *sr* for serpentine receptor, the exception being the *str* family, which stands for seven-transmembrane domain (Troemel, E. R. *et al.*, 1997).

The *CeCr* genes share many of the characteristics common to insect ORs inasmuch as they are very divergent, both within and between families (Robertson, H. M. and Thomas, J. H., 2006). While their topology places them squarely within the GPCR superfamily, their phylogenetic relationships to insect ORs have not been fully explored, making it difficult to address whether they share a common chemoreceptor lineage or were derived independently (Figure 4). What is clear is that the *CeCrs* cluster on a massive scale in the *C. elegans* genome (Figure 3). As a rule, closely related genes tend to be located near each other (Robertson, H. M., 2000; 2001; Chen, N. *et al.*, 2005). Similar to other invertebrate *Ors*, *CeCrs* contain small introns (Robertson, H. M., 1998; 2000). One distinguishing overall characteristic of the *CeCr* gene products is their small size (Figure 6). As we have already noted above, insect ORs have an average length of about 400 AA. However, the *CeCr* peptides are generally predicted to have lengths of 350 AA or less, resulting in smaller loop regions between predicted transmembrane domains (Troemel, E. R. *et al.*, 1995; Robertson, H. M., 1998; Robertson, H. M., 2000; Chen, N. *et al.*, 2005; Robertson, H. M. and Thomas, J. H., 2006 #3625). Finally, the small number of chemosensory neurons (<40) relative to the large number of *CeCrs* implies that multiple chemoreceptor proteins must be expressed in single sensory neurons (Figure 1) (Bergamasco, C. and Bazzicalupo, P., 2006), a feature that is not shared with insect ORs that are thought to express a single conventional *Or* (Ache, B. W. and Young, J. M., 2005).

Although not all *CeCrs* are expected to act as traditional ORs, sensitive to volatile odorants, we will consider them together as one large superfamily with the understanding that future studies will begin to elucidate the spectrum of *CeCr* functions. A recent review summarizes the size and the diversity of the *CeCr* superfamily in this way, "This large genetic investment might result from an extreme dependence on chemosensory abilities in the absence of visual and auditory systems. On the basis of genetic complexity, this system probably constitutes the bulk of signal transduction that occurs in *C. elegans*" (Robertson, H. M. and Thomas, J. H., 2006). Furthermore, the completion of the *Caenorhabditis briggsae* genome allowed comparative studies of candidate chemoreceptors between *C. elegans* and *C. briggsae*, species that have diverged 80–110 mya (Stein, L. D. *et al.*, 2003) and revealed extreme divergence between the two *Cr* repertoires resulting from frequent amplifications of *CeCrs* relative to their *C. briggsae* counterparts (Robertson, H. M. and Thomas, J. H., 2006).

4.33.3.3.2.(i) Str/srh gene families The phylogenetically related *str* and *srh* genes are the largest individual *CeCr* families together comprising about 600 genes (Robertson, H. M. and Thomas, J. H., 2006). Phylogenetic studies of *str*/*srh* genes within *C. elegans* and between C. *elegans* and *C. briggsae* suggest that these receptors are in a constant state of change driven by the processes of gene duplication, deletion, intron gain and loss, and movement within the respective genome (Robertson, H. M., 1998; 2000; 2001). Interestingly, many of the nearly 200 apparent *str* and *srh* pseudogenes in the N2 strain encode full-length *CeCr* proteins in other nematode strains (Stewart, M. K. *et al.*, 2005). This finding and the discovery of several other nucleotide polymorphisms indicate extensive gene diversity in wild *C. elegans* populations

(Stewart, M. K. *et al.*, 2005). Incredibly, more than 80% of the *str* and *srh* genes are concentrated on chromosome V (Robertson, H. M., 1998; 2000; 2001; Robertson, H. M. and Thomas, J. H., 2006). This intriguing theme is repeated for most other *CeCr* loci (Figure 3) (Ono, Y. *et al.*, 2005; Robertson, H. M. and Thomas, J. H., 2006).

4.33.3.3.2.(ii) Sra/srab gene families The *sra* and *srab* are two of the smaller *CeCr* families, but important in the amount of attention they have received. The *sra* genes were among the first candidate *CeCrs* identified (Troemel, E. R. *et al.*, 1995). This *sra* family is composed of 32 genes and 7 pseudogenes (Robertson, H. M. and Thomas, J. H., 2006). Twenty-two *srab* genes and five pseudogenes were recently identified based on their similarity to the *sra* genes (Chen, N. *et al.*, 2005). Both *sra* and *srab* families have an average translation of about 330 AA (Robertson, H. M. and Thomas, J. H., 2006). *Sra* genes are concentrated on chromosomes I and II, while the *srab* genes are almost all located on chromosome V and nearly all *srab* family members lack an *sra*-defining protein motif, and phylogenetic analysis clearly segregates them into a distinct subfamily (Chen, N. *et al.*, 2005). There are small numbers of orthologues between *sra* and *srab* genes in *C. elegans* and *C. briggsae* based on sequence alignments and genome synteny (Chen, N. *et al.*, 2005). Those *C. elegans*/*C. briggsae* gene pairs that are existent are substantially diverged and are not considered to be true orthologues (Robertson, H. M. and Thomas, J. H., 2006). Furthermore, the *sra* and *srab* gene families are significantly expanded in *C. elegans* relative to *C. briggsae* due to apparent duplication events in *C. elegans* (Chen, N. *et al.*, 2005).

4.33.3.3.2.(iii) CeCr function Genetic studies have supported a chemoreceptive role for selective *CeCr* genes. Certainly, the most compelling example of this is the characterization of *odr-10*, an *str* family member that encodes a receptor mediating the olfactory response to diacetyl (Sengupta, P. *et al.*, 1996). *Odr-10* remains the sole *CeCr* with an identified ligand (Figure 5).

In the absence of additional functional studies, numerous investigations have examined *CeCr* expression patterns as a means of supporting their classification as chemoreceptors. For example, four *sra* genes were expressed in chemosensitive amphid neurons in the head (Troemel, E. R. *et al.*, 1995) while expression of three *srab* genes was observed in tail chemosensitive neurons, two of those also showing expression in head chemosensory neurons (Chen, N. *et al.*, 2005). *Str-2* is expressed only in AWC neurons (Colosimo, M. E. *et al.*, 2003) and *odr-10* is expressed in AWA neurons (Sengupta, P. *et al.*, 1996). Furthermore, while a summary of the data from several promoter: Green Fluorescent Protein (GFP) expression studies illustrates that most *CeCrs* (48/63) are expressed in sensory tissues while many others (15/63) are not (Robertson, H. M. and Thomas, J. H., 2006). Another study identified a promoter element, common to numerous *srh* and *sri* genes, that is capable of ectopically driving *odr-10* expression in the ADL neuron (McCarroll, S. A. *et al.*, 2005). Finally, a microarray-based study determined that five *CeCrs* were among the most prevalent genes expressed in the RNA derived from the AWB neuron, a result confirmed by promoter:GFP experiments (Colosimo, M. E. *et al.*, 2004).

While many of the experiments described above support a chemoreceptive function for *CeCrs*, the supposition that all *CeCr* gene products act either as volatile ORs or soluble tastant receptors remains tenuous at best. Multiple *CeCrs* from different families, as suggested either by their similarities to other genes with known function, expression patterns, or mutant phenotypes, might well have other functions. For example, the *srw* family shares its origins with FMRFamide and other peptide receptors (Robertson, H. M. and Thomas, J. H., 2006). Although a proposed role for the *srw* gene as environmental peptide receptors has merit, some of these 145 genes may operate in other capacities, perhaps as cell–cell communication receptors. In fact, at least one *CeCr* does not seem to function as a chemoreceptor at all. *sra-11* is expressed in interneurons downstream of sensory neurons and an *sra-11* null mutation disrupts olfactory imprinting, a specific type of olfactory-driven memory (Remy, J.-J. and Hobert, O., 2005) for at least two different odorants suggesting that *sra-11* has a general role in the process. While it seems likely that the majority of *CeCrs* do indeed act as receptors of environmental stimuli, much more study is required to fully appreciate the multiplicity of receptive roles, both external and internal, that this large superfamily may or may not carry out.

4.33.4 Signaling Cascade

For better or worse, the identification of genes involved in olfactory transduction in invertebrates has historically been restricted to the molecular

context derived from the knowledge acquired in the vertebrate visual and olfactory systems. These pathways have been elegantly studied and extensively reviewed elsewhere (Hildebrand, J. G. and Shepherd, G. M., 1997), and molecular, cellular, and genetic studies indicate that, for the most part, similar gene families are required in invertebrate olfactory transduction. Even so, it is essential to appreciate that several studies elaborated in this chapter have pointedly demonstrated that insect olfactory systems display several unique characteristics that argue against a wholesale acceptance of vertebrate signal transduction paradigms. Indeed, the novel function and conformation of both nonconventional and conventional ORs in Drosophila has fostered the suggestion that insect chemosensory transduction processes may in fact involve non-GPCR mechanisms (Benton, R. *et al.*, 2006).

4.33.4.1 Guanine Nucleotide-Binding Proteins and Effector Genes

4.33.4.1.1 Insects

GPs are a heterotrimeric assemblage of an alpha (α), beta (β) and gamma (γ) subunits as ancient as the eukaryote divergence (Jones, A. M. and Assmann, S. M., 2004). GPs may best be considered as molecular switches: located in the cell membrane, they modulate the activity of a variety of intracellular effector molecules once activated by GPCRs. Although the exact mechanism of GPs activation remains ambiguous, odorant-induced conformational change of the GPCR is likely to be required. The Gα subunit in particular seems to be interacting directly with the OR since both visual and olfactory systems rely on GPCRs (Grobner, G. *et al.*, 2000; Vogt, R. G., 2006).

Six Gα genes have been identified in the genomes of *D. melanogaster* and *An. gambiae* (Figure 3). *An. gambiae* $G_q\alpha$ (*agq*), *ago*, *agi*, and *agm* are located within a large 24-Mb segment on chromosome 2L while *ags* and *agc* are located on 3L and 3R, respectively. Phylogenetic analysis supports that *ago* and *agi* derive from a common ancestor as suggested by their relative genomic proximity (~3 Mb) (Rutzler, M. R. *et al.*, 2006). Drosophila Gα genes (*dg*) are located ~2 Mb apart on 2R and 3L with *dgo* and *dgq*. Importantly, splice variants of $G_q\alpha$ are components of the phototransduction pathway and are also expressed in chemosensory cells (Scott, K. *et al.*, 1995; Talluri, S. *et al.*, 1995). According to immunolocalization studies, $G_q\alpha$ protein is associated to the dendrite of *B. mori* and *An. gambiae* ORN (Laue, M. *et al.*, 1997; Rutzler, M. R. *et al.*, 2006), and functional evidence for $G_q\alpha$ requirement in olfactory transduction has been provided by RNAi mediated silencing experiments in the Drosophila antenna (Kalidas, S. and Smith, D. P., 2002). In these studies, altered olfactory responses were odor-dependent suggesting that there are more than one type of olfactory GP or, indeed, that alternative transduction mechanisms coexist.

In fact, molecular and electrophysiological approaches provide support for the hypothesis that two transduction pathways may be active in invertebrate olfactory transduction. One depends on the second messenger 1,4,5 inositol triphosphate (IP3) and the other depends on cAMP. In the lobster *Panulirus argus*, both cAMP and IP3 pathways are activated in response to stimulation with complex odor mixtures suggesting that both an AC and a PLC are targeted (Boekhoff, I. *et al.*, 1994).

A PLCβ is almost certainly involved in the olfactory transduction pathway of insects. In Drosophila, olfactory and visual physiology is dependent on the activity of the *norpA* PLC gene, which acts downstream of GPs (Riesgo-Escovar, J. *et al.*, 1995) although *norpA* activity in olfactory tissues is thus far restricted to the maxillary palp. The transient increase of IP3, a breakdown product of PIP2 by PLC, following exposure to odorants also supports a GP-mediated transduction pathway in insects (Breer, H. *et al.*, 1990). In Drosophila, recovery from olfactory adaptation is mediated by a phosphatidylinositol transfer protein gene dubbed *retinal degeneration B* (*Rdgb*), (Riesgo-Escovar, J. R. *et al.*, 1994). *Rdgb* mutants display delayed return to the resting potential following exposure to odorants. *Rdgb* encodes a six-transmembrane domain protein, which contains Ca^{+} binding domains involved in IP3 formation. In addition to being expressed in the eye, this gene is present in the antenna, labellum, and maxillary palp where it is thought to play a role in membrane metabolism.

Mutations of the Drosophila rutabaga (*rut*) and dunce (*Dun*) genes affect the cAMP transduction pathway (Martin, F. *et al.*, 2001; Gomez-Diaz, C. *et al.*, 2004). *Rut* and *Dun* encode an AC and a cAMP-PDE, respectively. Both genes express in the antenna, and the mutants exhibit defective electrophysiological and behavioral olfactory responses coherent with the initial stage of odorant transduction. Both genes are members of small families: six ACs and two cAMP-PDE have been identified in the fly genome.

4.33.4.1.2 *Caenorhabditis elegans*

Twenty-one $G\alpha$ genes are in the genome of *C. elegans* (Jansen, G. *et al.*, 1999; Bergamasco, C. and Bazzicalupo, P., 2006). Two clusters of five and nine genes are located on chromosomes I and V, respectively. Phylogenetic analysis shows that there is one orthologue for each of the four vertebrate $G\alpha$ subunits ($G\alpha_{o/i}$, $G\alpha_s$, $G\alpha_q$, and $G\alpha_{12}$) sharing over 68% amino acid identity (Roayaie, K. *et al.*, 1998). *C. elegans* GPs are widely expressed in the nervous system but six $G\alpha$ subunits are expressed in the two pairs of AWA and AWC neurons that mediate odorant attraction (Bargmann, C. I. *et al.*, 1993; Troemel, E. R. *et al.*, 1995; 1997; Jansen, G. *et al.*, 1999). Based on GFP fusion constructs and immunocytological studies, five $G\alpha$ proteins (GPA-2, GPA-3, GPA-5, GPA-13, and ODR-3) are localized to the ciliated dendrites suggesting that they presumably interact with GPCRs in a complex signaling network (Jansen, G. *et al.*, 1999; Lans, H. *et al.*, 2004).

In *C. elegans*, GP targets are likely to include AC and guanylyl cyclase (GC), cGMP-PDE and phospholipases. While in vertebrate, olfaction CNG channels activation is mediated by an AC/cAMP pathway, this role is performed in *C. elegans* by GCs. Two transmembrane GP-sensitive GCs (tGCs) are clearly required for chemosensory transduction in *C. elegans*. Both ODR-1 and DAF-11 (abnormal *da*uer *f*ormation) are located in the cilia of various chemosensory neurons including the olfactory neuron AWC (Birnby, D. A. *et al.*, 2000; L'etoile, N. D. and Bargmann, C. I., 2000). At least 26 additional transmembrane and 7 soluble GC genes have been identified in the *C. elegans* genome, suggesting that this organism favors cGMP over cAMP second messengers to activate downstream ion channels. Phylogenetic analyses show that 21 of the tGCs form a lineage-specific expansion that correlates with the proximity of these genes on the chromosomes (Fitzpatrick, D. A. *et al.*, 2006).

4.33.4.2 Ion Channels

CNG and TRP ion channels function in many vertebrate sensory transduction pathways. *Drosophila* and *C. elegans* each have four and six CNG channel genes, respectively, and at least two reports suggest that ion channel genes are active in Drosophila olfaction. One gene encodes an apparent vertebrate CNG Ca^+ channel homolog (*Dmel*CNG) and the gene *ether a go-go* (*eag*) encodes a putative cyclic nucleotide-modulated K^+ channel (Baumann, A. *et al.*, 1994; Dubin, A. E. *et al.*, 1998). *Dmel*CNG is expressed in the antennal and eye tissues and physiological studies suggest that this is a Ca^+ channel modulated by cGMP (Baumann, A. *et al.*, 1994). Mutant *eag* flies exhibit defective olfactory phenotype in a subset of olfactory sensilla (Dubin, A. E. *et al.*, 1998). Although not related to *Dmel*CNG, the *eag* gene also requires cyclic nucleotides for activity and contains a consensus cyclic nucleotide-binding site. No other ion channels have been identified as possible downstream target of effector genes in primary olfactory sensing. However, there is one report suggesting that a TRP channel is involved in olfactory adaptation in the developing Drosophila antenna (Stortkuhl, K. F. *et al.*, 1999), but this gene could not be detected in mature adult antenna. Lastly, an ITPR is expressed strongly in this tissue and is required for the maintenance of olfactory adaptation (Deshpande, M. *et al.*, 2000).

The *C. elegans* CNG consists of the α-subunit TAX-2 (abnormal chemo*tax*is) and the β-subunit TAX-4 involved in thermosensation and chemosensation (Coburn, C. M. and Bargmann, C. I., 1996). TAX-2 and TAX-4 are most similar to the vertebrate α and β subunits of the rod photoreceptors. Heterologous expression of TAX-2/TAX-4 has shown that this CNG channel is preferably activated by cGMP over cAMP and following its activation opens to Ca^+ currents (Komatsu, H. *et al.*, 1999) and loss of function mutants in either gene-display-defective chemotaxis to a subset of volatile compounds in the AWC and AWB neurons (Coburn, C. M. and Bargmann, C. I., 1996).

In contrast to the TAX-2/TAX-4 CNG channel that is active in AWB and AWC neurons, most chemosensory neurons in *C. elegans* use a TRP (vanilloid-related subfamily)-related ion channel for primary sensation and adaptation (Colbert, H. A. and Bargmann, C. I., 1995) whose closest vertebrate homologue is the nociceptive capsaicin receptor (Minke, B. and Cook, B., 2002). The *C. elegans* genome harbors five *trp* genes including *osm-9* (abnormal *osm*otic avoidance) and four *ocr* genes (*osm-9*/*c*apsaicin *r*eceptor-related). Combinations of OSM-9 and OCR subunits determine the function of the resulting TRP channels (Tobin, D. *et al.*, 2002). *Osm-9 lf* mutants in the AWA and ASH neurons exhibit strong chemosensory defects caused by the suppression of calcium currents after stimulation with a wide range of odorants. This suggests that most, if not all, transductory signaling converges on this ion channel. In the AWA and ASH neurons, OSM-9 requires OCR-2 for signal transduction and both are located

on the ciliated end of the dendrite (for review, see Bergamasco, C. and Bazzicalupo, P., 2006). In the AWC neuron, OSM-9 alone is involved in olfactory adaptation, negatively modulating olfactory responses to prolonged odor exposure (Colbert, H. A. and Bargmann, C. I., 1995).

4.33.5 Regulators of Signaling

4.33.5.1 Arrestins and G-Protein-Coupled Receptor Kinases

In mammalian systems, signal termination is mediated by two small gene families: GPCR kinases (GRKs) and ARRs. GRKs phosphorylate activated GPCRs, which are in turn targeted by ARRs, which disrupts the GPCR–GP complex (Krupnick, J. G. *et al.*, 1997). This promotes several events including clathrin-mediated receptor internalization/degradation and other downstream pathways (for reviews, see Lefkowitz, R. J. and Shenoy, S. K., 2005; Reiter, E. and Lefkowitz, R. J., 2006).

Thus far, two putative Drosophila (*DmGrk1* and *DmGrk2*) and two *C. elegans* GRKs (*Ce-Grk-1* and *Ce-Grk-2*) have been identified (Cassill, J. A. *et al.*, 1991; Fukuto, H. S. *et al.*, 2004; Reiter, E. and Lefkowitz, R. J., 2006). Not surprisingly, invertebrate *Grk* genes share considerable homology with their vertebrate counterparts. *Ce*-GRK1 and *Ce*-GRK-2 are 56% and 66% identical with human GRK5 and GRK3, respectively. *DmGrk1/2* and *Ce-Grk2* are broadly expressed throughout development and in various tissues including the CNS suggesting that they may function in multiple developmental and neuronal pathways. While the function of *Grk* genes in Drosophila olfaction has not been established, *Ce-grk2* (*lf*) mutants exhibit a significant chemosensory defect consisting of a loss of response to octanol (Fukuto, H. S. *et al.*, 2004).

As is the case for vertebrates, four *arrestin* genes have been identified in the genome of *D. melanogaster* and *An. gambiae* (*DmArr1-4* and *AgArr1-4*, respectively). *DmArr1* and *DmArr2* are expressed in photoreceptors and ORNs (Merrill, C. E. *et al.*, 2002). Consistent with a role in olfactory signal transduction, hypomorphic alleles of both *DmArr1* and *DmArr2* display significant reductions in olfactory responses to various odorants, and *DmArr1* larvae show defective chemotaxis in behavioral experiments (Merrill, C. E. *et al.*, 2005). Interestingly, these phenotypes are variable depending on odorants stimuli suggesting that in insect ORNs, *Arr1* and *Arr2* may participate in two independent desensitization pathways.

There are four subclasses of insect ARRs based on sequence similarity. Insects *Arr1* and *Arr2* encode approximately 400 AA proteins. They are referred to as sensory ARRs because of their broad expression in the olfactory and visual tissues. However, while the ARR1 primary amino acid sequence contains all the conserved domains of vertebrate ARRs, ARR2 lacks the C-terminal clathrin binding domain (Merrill, C. E. *et al.*, 2002; 2003). *Arr3* genes on the other hand encode considerably larger proteins and include the *D. melanogaster Kurtz* (*DmKrz*), a gene expressed throughout development in a multitude of tissues including the nervous system (Roman, G. *et al.*, 2000) and mutations in which larval are lethal. *Arr3* genes exhibit most of the canonical motifs found in vertebrate nonvisual ARRs. The fourth subclass of ARR genes (*Arr4* alleles) is significantly different from the other types, hence their annotation as atypical.

In contrast, the *C. elegans* genome apparently encodes a single ARR (*Ce-Arr1*) gene, which shares significant sequence homology to vertebrate nonvisual ARRs (65% similarity) and is most similar to the nonsensory ARR3/KURTZ ARR subtypes with 70% amino acid similarity, including well-characterized motifs known to interact with various molecular partners (Palmitessa, A. *et al.*, 2005). However, in contrast to *Kurtz*, *Ce-Arr1* mutants in *C. elegans* are viable and develop normally. Interestingly, while null mutants fail to adapt the following odorant stimulation, adaptation is restored in the C-terminal-truncated *Ce-Arr1* rescue mutant albeit with reduced recovery from adaptation capabilities demonstrating a dual role for *Ce-Arr1* in adaptation and recovery from adaptation in the AWC neuron. Although expressed broadly throughout the nervous system, *Ce-Arr1* is more highly expressed within the AWA, AWB, AWC, ASH, and ADL chemosensory neurons, where it overlaps with the expression of sensory GPs as described above. Palmitessa A. *et al.* (2005) determined that desensitization and adaptation require the N-terminal region to prevent the phosphorylated GPCR from interacting with the GP, while recovery from adaptation depends on the various components of the endocytic machinery and is mediated by the C-terminal domain.

4.33.5.2 The Caenorhabditis elegans Calcineurin TAX-6

The vertebrate calcineurin is a Ca^{+}/calmodulin (CaM)-dependent protein phophatase that acts as a positive regulator of calcium-dependent signals in

various biological pathways. The CaM and the B-subunit are required to activate the catalytic activity of the A-subunit. Ce-TAX-6 is 77% identical to the A-subunit (Kuhara, A. *et al.*, 2002). A putative homolog of the B-subunit has been identified in the worm genome and share 80% amino acid identity with its vertebrate counterpart. *Tax-6* mutants display several phenotypes indicating the pleiotropic nature of this gene. In the AWC neuron, *tax-6* mutants display diminished olfactory responsiveness reflected by enhanced adaptation when exposed to various odorants. The mechanism underlying this chemosensory is unknown but it requires the presence of a functional TRPV OSM-9 channel.

4.33.5.3 Other Protein Kinases

In addition to the core components of olfactory signal transduction thus far discussed, there is good evidence that implicates an ever increasing set of protein kinase-associated pathways in invertebrate chemosensory processes. Indeed, in further support of IP3-based second messenger pathways in insect olfactory transduction cascades is the identification of the Drosophila *IP3 kinase1* gene (*IP3K1*) (Gomez-Diaz, C. *et al.*, 2006). IP3K1 mediates IP3 degradation and is expressed in multiple locations including the olfactory appendages and the head. Importantly, gain-of-function *IP3K* Drosophila mutants exhibit diminished olfactory sensitivity due to increased recovery times (Gomez-Diaz, C. *et al.*, 2006).

In *C. elegans*, the signal termination in the AWC olfactory neuron is characterized by short- and long-term adaptation components that are mediated by a cGMP-dependent kinase (EGL-4) (L'etoile, N. D. *et al.*, 2002). EGL-4 and mammal protein kinase G (PKG) share similar functional domains including cGMP-binding motifs and a serine/threonine kinase domain (L'etoile, N. D. *et al.*, 2002). The latter domain has been shown to regulate the TAX-2/TAX-4 CNG channel by targeting a specific phosphorylation site on the TAX-2 subunit. A longer adaptation mechanism seems to be mediated by EGL-4 nuclear translocation and by regulation of gene expression. This mechanism is present in mammalian systems and is assumed by PKG (Gudi, T. *et al.*, 1997).

Expression and mutant analyses show that the protein kinase C (PKC) genes *ttx-4* and *tpa-1* are involved in multiple sensory pathways including olfaction (Okochi, Y. *et al.*, 2005). These genes encode protein homologs to the human novel PKC (over 50% amino acid identity) and Drosophila PKC (60% amino acid identity), and both have Di Acyl Glycerol-binding domains. The chemotaxis defects observed in *ttx-4* and *tpa-1 lf* mutants are rescued by an exogenous DAG analog implicating these two genes in the regulation of the second messenger pathway pertaining to olfactory sensation.

Lastly, five DAG kinase genes (*dgk*) have been identified in the *C. elegans* genome of which *dgk-1* and *dgk-3* act redundantly to reduce DAG levels and have been shown to participate in olfactory adaptation (Matsuki, M. *et al.*, 2006). The effects of DAG and other genes known to participate in DAG-mediated pathways provide strong support that phospholipase-based effectors are active in this complex regulatory network. Still, the jury is out as to the precise mechanisms underlying olfactory signaling within the invertebrate systems under study. At this point there is a growing body of circumstantial evidence but, if we may take the courtroom analogy one step further, no smoking gun to provide hard proof implicating any specific pathway(s).

4.33.6 Conclusion and Perspectives

The study of the olfactory subgenomes of insects and worms indicate that olfactory organs use similar gene families for the detection and conversion of chemical signals. Whether these shared molecular strategies are the result of evolutionary convergence as a response to a common chemical environment and/or a reflection of shared ancestry is difficult to discern. The large *Obp*/*Or* gene families described in this chapter display elements of similar genomic dynamics. For example, the majority of genes in a given family within a given genome occur in clusters and their phylogenetic relations surely reflect sequence homology that often correlates with cytogenetic position implying that local gene expansion has resulted from intrachromosomal gene duplications. It can also be reasonably argued that sequence homology between vertebrate and invertebrate gene families, in particular in the components of signal transduction, provides strong support for shared ancestry. Although important, this maxim is not so evident in the case of the chemosensory GPCRs and OBPs, which may represent two genetic interfaces between the ORN and the odors. The repertoires of these gene families are highly divergent even within species with only few orthologues shared between species. This type of comparison clearly indicates that this family displays lineage-specific expansions and reductions indicating ongoing genetic turn over and rapid evolution.

All GPCRs are presumed to have seven-transmembrane domains and interact with highly conserved or analogous transductory elements. The identification of which is the result of both directed research based on the mammalian olfactory and visual systems and also through discovery-based approaches epitomized by the use of forward genetic screens. Whereas both worms and insects use GPCRs as the initial recognition step, insects have developed a singular mechanism requiring the combination of a generic nonconventional GPCR and an odorant-specific conventional OR. While it appears likely that this unique adaptation is profound and may be specific to arthropods, the functional implications of this mechanism within these taxa remain unknown. In addition, the proposed reverse topology of insect ORs potentially makes this system truly novel as it adds a level a complexity in the molecular architecture of olfactory transduction. Interestingly, despite all these structural differences and sequence divergence, GPCRs of vertebrate and invertebrate interact with conserved GPs.

An equally striking difference between insects and worms resides in the divergent molecular strategies observed upstream of the chemosensory GPCRs. While insects have a moderate number of *Ors* and *Obps*, worms do not have *Obps* but have a much larger *Or* repertoire. It has been proposed that OBPs contribute to the odor coding by interacting with the ORs. But as we pointed earlier, there are very few reports suggesting a strict requirement of these proteins for proper olfactory function. Also, the number of authentic *C. elegans* chemoreceptors are probably smaller as indicated by a recent research.

Overall, it is certain that the number of genes involved in olfactory pathways will increase as more genetic screens and reverse genetic tools are applied to invertebrate systems. The most challenging task lays ahead in forging an understanding of the regulation and the network of epistatic interactions among olfactory genes that serve to provide the basis for the downstream processing of olfactory information that ultimately results in learning, memory, and which form the basis for critical behavioral decisions.

4.34.1 Introduction and Early Literature

The capacity of the olfactory epithelium (OE), especially its population of sensory neurons, to recover after injury, reconnect with the central nervous system (CNS), and reestablish function has been known from the first half of the twentieth century (Nagahara, Y., 1940). In addition to experimental studies on the consequences of transection of the olfactory nerve (ON) along its course from the OE to the olfactory bulb (OB), an extensive literature documents sensory recovery in humans in the large cohort of children and young adults who were treated by irrigation with zinc sulfate as a means of polio prophylaxis. Subsequent experimental investigations demonstrated anatomical reconstitution of the epithelium following zinc sulfate treatment in a variety of experimental species, including primates (Schultz, E. W., 1941; Schultz, E. W. and Gebhardt, S. P., 1942; Schultz, E. W., 1960; Mulvaney, B. D. and Heist, H. E., 1971; Matulionis, D. H., 1975; 1976). Studies performed by Graziadei, Moulton, and colleagues in the 1960s and 1970s demonstrated that the epithelium of laboratory animals harbored a population of rapidly proliferating cells that functioned as neuronal progenitors and gave rise to neurons (Moulton, D. G. *et al.*, 1970; Graziadei, P. P. and Metcalf, J. F., 1971; Graziadei, P. P., 1973; Moulton, D. G., 1974; Graziadei, P. P. C. and Monti Graziadei, G. A., 1978; Graziadei, P. P. and Monti Graziadei, G. A., 1979). This remarkable and seminal discovery invigorated the cellular and molecular investigations of olfactory neurogenesis, which have carried on to this day.

From a teleological perspective, the persistence of neurogenesis in the normal adult OE and the anatomical and functional recovery following injury to the epithelium or the nerve are highly adaptive. The epithelium is particularly vulnerable to any number of toxins, infectious agents, or other forms of insult, given the direct contact of the neural elements with the ambient, airborne environment. Moreover, the neurons and their axons form a direct conduit from the outer world into the CNS that may be used as a route of entry to the brain by pathogens, such as neurotropic viruses (Twomey, J. A. *et al.*, 1979; Monath, T. P. *et al.*, 1983; Stroop, W. G. *et al.*, 1984; Barnett, E. M. *et al.*, 1993; Barnett, E. M. and Perlman, S., 1993). Thus, a propensity for the neurons to die with little provocation may provide a survival advantage in the short term for the organism by preventing the transmission of pathogens, but requires some capacity for compensatory reconstitution of the system after the exposure period has passed.

The intent of this review is to summarize the current state of our knowledge regarding cellular renewal in the normal OE, the enhanced production of neurons and nonneural cell types after injury, reinnervation of the bulb following epithelial reconstitution, and restoration of sensory function subsequent to anatomical recovery. We will not consider the vomeronasal system.

For heuristic purposes, our discussion will focus first on the epithelium and its capacity for reconstitution and then turn to the ON and its innervation of the bulb.

4.34.2 Structure of the Olfactory Mucosa: Layers and Compartments

The olfactory mucosa forms a continuous sheet lining the posterodorsal part of the nasal septum, the tips of the opposing nasal turbinates, and much of the turbinate shafts and cul-de-sacs at the same level (Moulton, D. G. and Beidler, L. M., 1967; Grazaiadei, P. P. C., 1971). In addition, a small patch of olfactory mucosa, termed the nasal septal organ (NSO) (of Masera), detaches from this sheet at an early embryological stage and comes to reside just dorsal to the opening of the nasopharyngeal duct (Bojsen-Moller, F., 1975; Weiler, E. and Farbman, A. I., 2003); the NSO is, for all intents and purposes, identical to the main OE in morphology, molecular phenotype, and function, and will not be considered separately (Taniguchi, K. *et al.*, 1993).

The olfactory mucosa consists of a pseudostratified epithelium and a lamina propria that rests directly on the bony and cartilagenous skeleton of the nose (de Lorenzo, A. J., 1957; Andres, K. H., 1966; Moulton, D. G. and Beidler, L. M., 1967; Grazaiadei, P. P. C., 1971; Graziadei, P. P. and Monti Graziadei, G. A., 1979). The epithelium contains a handful of cell types: neurons, supporting cells and basal cells (Figure 1(a)). Each of these categories may be further subdivided.

4.34.2.1 Sensory Neurons

The population of neurons consists of both mature, ciliated, olfactory marker protein (OMP)-expressing and immature, GAP-43 (+) cells that have yet to

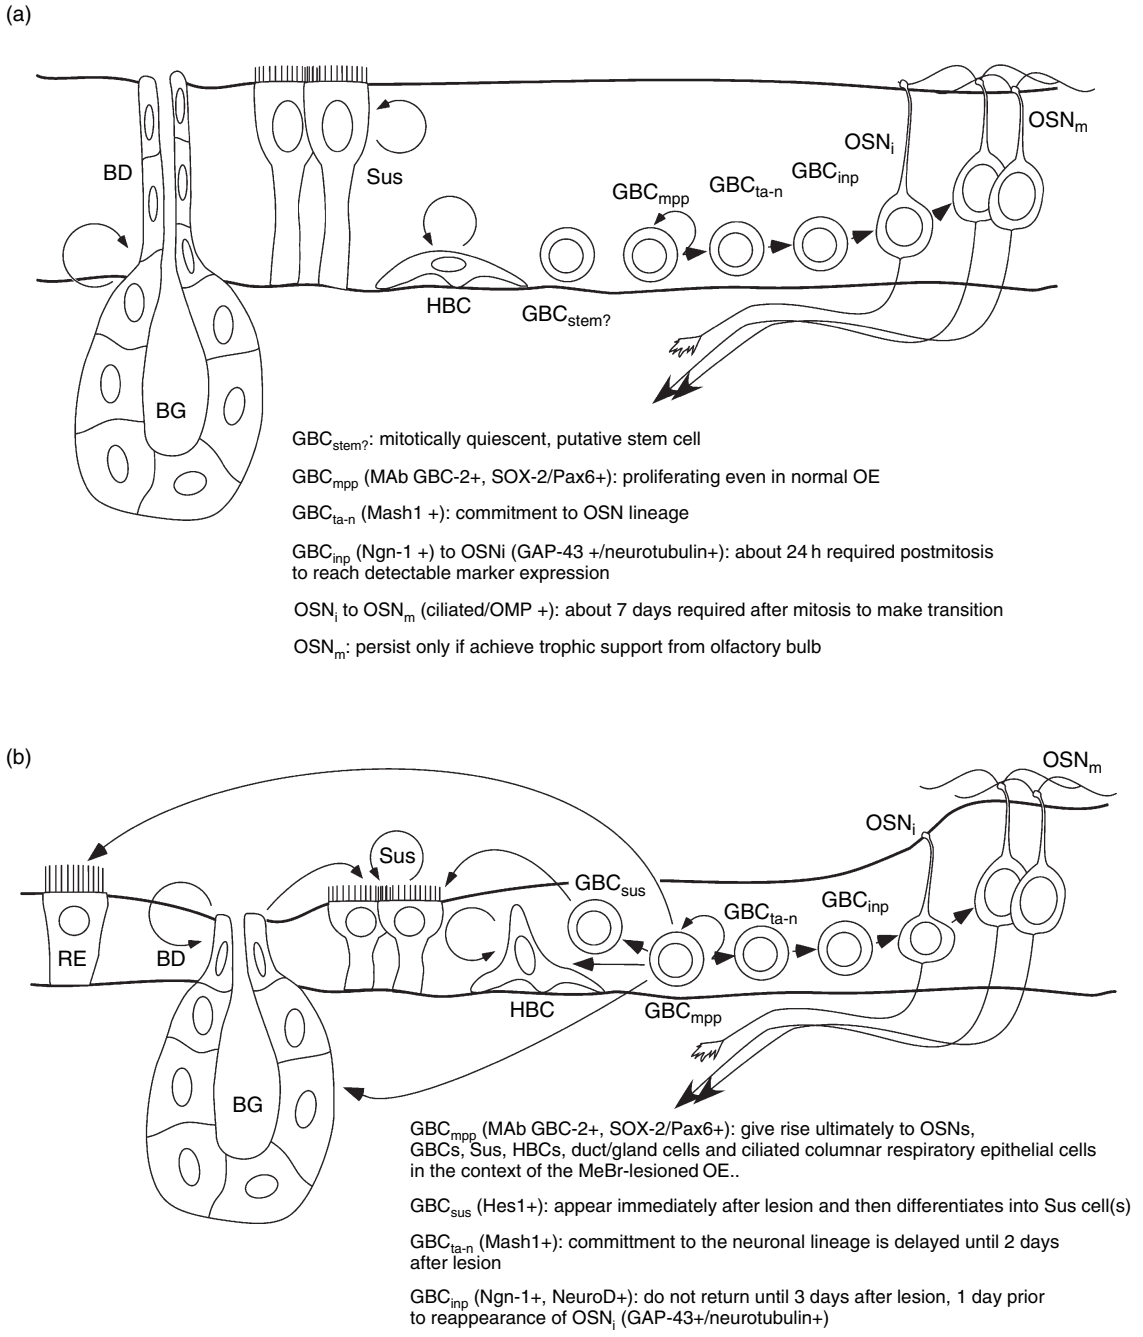

Figure 1 The processes of cellular renewal differ between normal and lesioned olfactory epithelium. (a) In normal epithelium or in epithelium in which the population of neurons has been depleted as a consequence of acute damage to olfactory nerve or bulb or where neuronal turnover is accelerated for neurons born following bulb ablation, the various cell types arise via self-replacement or, in the case of the sensory neurons, from the mitosis of globose basal cells (GBC). (b) In contrast to the foregoing, following methyl bromide exposure, more promiscuous lineage relationships emerge: GBCs will give rise to neurons and themselves (a form of self-renewal), of course, but also to horizontal basal cells (HBCs), sustentacular (Sus) cells, Bowman gland (BG), and duct (BD) cells, and even respiratory epithelial (RE) cells. In essence, GBCs are demonstrably as potent in the context of the nasal epithelium as the cells of the olfactory placode. BD cells also evince a greater than normal potency and contribute to the replacement of the Sus cell population. The GBC population is heterogeneous with respect to functional phenotype, and the various kinds can be distinguished on the basis of their expression of member of various transcription factor families.

elaborate cilia (Verhaagen, J. *et al.*, 1989; Meiri, K. F. *et al.*, 1991). The population of typical olfactory neurons can be subdivided further on the basis of which single odorant receptor (OR) is expressed from among the family of about 1300 OR genes (Buck, L. and Axel, R., 1991; Zhang, X. and Firestein, S., 2002). That choice is constrained by a neuron's position along the dorsomedial-to-ventrolateral axis of the epithelium. Along that axis, each OR is limited to a narrow band that reaches through the anteroposterior extent of the OE (Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993). Although the spatial organization has been described as sharply bounded and zonal, more recent studies suggest that each OR-defined band overlaps partially with a number of other ones (Iwema, C. L. *et al.*, 2004; Miyamichi, K. *et al.*, 2005). As a consequence, the organization of OR expression across epithelial space is better described as a very large number of bands that gradually shift in position along that dorsomedial-to-ventrolateral axis, rather than a very small number of zones. From a developmental perspective, the organization in shifting, sharply bounded bands is as easily explained as the four-zone model; for example, a cell's response to a gradient of a signaling molecule can generate shifting bands as easily as a discrete number of stripes (Wolpert, L., 1989). Other features of the neuronal phenotype are also position-dependent including connectivity and expression of certain cell-surface markers, and may also be sharply bounded (Mori, K. *et al.*, 1985; Schwob, J. E. and Gottlieb, D. I., 1986; 1988, Schwarting, G. A. and Crandall, J. E., 1991; Schwarting, G. A. *et al.*, 1992; Yoshihara, Y. *et al.*, 1997).

In addition to the foregoing, atypical olfactory neurons are concentrated in (but not limited to) the epithelium lining the cul-de-sacs of the posterior nasal cavity, which differ from the majority. The sensory transduction apparatus is based on guanylyl cyclase expression rather than adenylyl cyclase; they lack OMP; finally, they project to the necklace glomeruli at the posterior edge of the glomerular sheet (Shinoda, K. *et al.*, 1989; 1993, Juilfs, D. M. *et al.*, 1997; Ring, G. *et al.*, 1997). The neurons elaborate thin unmyelinated axons that gather at the basal lamina under the arch-like process of the horizontal basal cells (HBCs) where the axons first come into contact with the glia of the ON.

4.34.2.2 Supporting Cells

The microvillar-capped supporting cells whose nuclei reside at the apex of the epithelium can be subdivided into sustentacular (Sus) and microvillar cells. Sus cells contain abundant smooth endoplasmic reticulum, while microvillar cells do not. Both express cytokeratins 8 and 18, but otherwise have different biochemical profiles: Sus cells stain with MAbs SUS-1 and SUS-4, while microvillar cells label with the MAb 1A-6, the lectin Iβ-4 from *Bandeiraea simplicifolia* (BS-I), and express ankyrin. Furthermore, other characteristics can be used to differentiate the two types of microvillar cells (Hempstead, J. L. and Morgan, J. I., 1985a; Goldstein, B. J. and Schwob, J. E., 1996; Asan, E. and Drenckhahn, D., 2005).

4.34.2.3 Basal Cells

The population of basal cells can be subdivided on the basis of their relationship to the basal lamina. Horizontal (or dark) basal cells (HBCs) attach directly to the basal lamina via desmosomes, express cytokeratins 5 and 14, the epidermal growth factor-receptor (EGF-R), intercellular adhesion molecule (ICAM), integrins, and a carbohydrate moiety recognized by the lectin BS-I (Graziadei, P. P. and Monti Graziadei, G. A., 1979; Holbrook, E. H. *et al.*, 1995; Carter, L. A. *et al.*, 2004).

Globose (or light) basal cells (GBCs) are situated at a remove from the basal lamina, and are distributed nonuniformly across the tangential extent of the epithelium (Graziadei, P. P. and Monti Graziadei, G. A., 1979; Holbrook, E. H. *et al.*, 1995; Loo, A. T. *et al.*, 1996). Conventionally, GBCs have been identified and defined on exclusionary grounds; cells have been classified as GBCs if morphologic simplicity and molecular phenotype indicate that they are not HBCs, not neurons, and not duct cells. A few positive markers have been generated, which are not strictly limited to the GBC population (Goldstein, B. J. and Schwob, J .E., 1996; Goldstein, B. J. *et al.*, 1997; Jang, W. *et al.*, 2003). For example, several monoclonal antibodies (MAbs) label GBCs along with neurons in normal epithelium, but not the other cell types. One of these MAbs – GBC-3 – binds to the 34 kDa, that is, immature, form of the laminin-receptor protein (iLRP) (Jang, W. *et al.*, 2007).

In addition, subsets of GBCs are labeled by a variety of TFs of the basic helix–loop–helix (bHLH), LHX, Msx, Pax, and SOX families, as well as others (Cau, E. *et al.*, 1997; 2000, Norlin, E. M. *et al.*, 2001; Cau, E. *et al.*, 2002; Suzuki, Y. *et al.*, 2003; Hirota, J. and Mombaerts, P., 2004; Kolterud, A. *et al.*, 2004; Guo, Z. *et al.*, 2005b). Thus, it appears that the

population of GBCs is markedly heterogeneous on biochemical grounds that likely correspond with differences in their capacities as progenitor cells.

A third type of basal cell has also been noted on ultrastructural grounds; it extends a foot process, contacts the basal lamina via an adherens junction, and is more irregularly shaped than most other GBCs (Graziadei, P. P. and Monti Graziadei, G. A., 1979; Holbrook, E. H. *et al.*, 1995). Some authors have considered these cells as a transition stage between HBCs and GBCs (or vice versa) (Graziadei, P. P. and Monti Graziadei, G. A., 1979), but no evidence other than morphological can be adduced for this notion. Because, in fact, the third type cells attach by adherens and not desmosomal junctions, there are really no data, morphologic or otherwise, to indicate intermediacy of this third type of basal cell or to draw a lineage relationship between GBCs and HBCs. However, little else is known about this type.

4.34.2.4 Bowman's Glands/Ducts

The final elements in the epithelium are Bowman's ducts, which extend from the Bowman's glands in the lamina propria to the apical surface where the mucus formed by the glands is discharged. The glands themselves are found within the lamina propria. The ducts and gland cells share some phenotypic characteristics with Sus cells, including a common reactivity with several MAbs and high expression of cytochrome P450s (Hempstead, J. L. and Morgan, J. I., 1985a; 1985b; Chen, Y. *et al.*, 1992; Huard, J. M. *et al.*, 1998).

4.34.2.5 Cells of the Lamina Propria

Other elements in the lamina propria include fibroblasts, migrating lymphocytes, and tissue macrophages. There may be other cell types within the lamina propria; for example, cells express retinoic acid (RA)-synthesizing enzymes at differential levels as a function of position along a dorsomedial-to-ventrolateral axis have not yet been fully characterized as to type. Whether fibroblastic or not, they may be critical for the reassembly of the system after lesion.

4.34.2.6 Fascicles of the Olfactory Nerve

The fascicles of the olfactory and vomeronasal nerve also course through the lamina propria. At a macroscopic level, the nerve begins as small bundles of axons that are evident where the basal lamina is breached. During their course posteriorward, the bundles gradually sink more deeply into the lamina propria where they obliquely contact, fuse with, and form larger fascicles of the nerve. The microscopic organization of the fascicles differs markedly from that of other peripheral nerves. The glia of the ON fascicles, termed olfactory ensheathing cells (OECs), are found within the perineurial sheath, which is formed by what have been termed ON fibroblasts (de Lorenzo, A. J., 1957; Andres, K. H., 1966; Barber, P. C. and Lindsay, R. M., 1982; Field, P. *et al.*, 2003; Li, Y. *et al.*, 2005). The perikarya of the OECs are found plastered against the edge of the nerve or of the endoneurial septae that subdivide the larger fascicles, while their processes interdigitate among the olfactory axons. In contrast to the mature spinal nerve in which single unmyelinated axons are segregated each within its own individual trough (Peters, A. *et al.*, 1991), collections of olfactory axons are in intimate contact with each other and isolated from the environment by the sheet-like processes of the OECs (de Lorenzo, A. J., 1957; Andres, K. H., 1966; Barber, P. C. and Lindsay, R. M., 1982; Field, P. *et al.*, 2003; Li, Y. *et al.*, 2005). In that respect, the relationship of bundles of olfactory axons and OEC glia in the adult is like that of the Schwann cell and axons of growing spinal nerves in the embryo, only writ large (Peters, A. *et al.*, 1991). The unique relationship between olfactory axons and glia begins within the pocket formed between the overarching processes of the HBCs and the basal lamina where the axons exit the epithelium and is maintained up to the entry of the axons into the neuropil of the olfactory glomeruli (Holbrook, E. H. *et al.*, 1995; Li, Y. *et al.*, 2005).

4.34.3 Ongoing Olfactory Neurogenesis

The intrinsic capacity of the OE to produce neurons throughout life was implicit in the demonstrations of structural and functional recovery by the olfactory system following experimental injury. However, a more direct understanding of the basis for ongoing neurogenesis came from the discoveries of the 1960s and 1970s by Graziadei, Moulton, and their respective colleagues that cells near the base of the OE in adult rodents incorporate labeled analogues of thymidine after pulse administration and that the thymidine-labeled cells can be chased with time and watched as they differentiate into neurons and then eventually disappear (Figure 1(a)) (Moulton, D. G. *et al.*, 1970; Graziadei, P. P. and Metcalf, J. F.,

1971; Graziadei, P. P., 1973; Moulton, D. G., 1974; Graziadei, P. P.C. and Monti Graziadei, G. A., 1978; Graziadei, P. P. and Monti Graziadei, G. A., 1979). During their cellular differentiation, the newborn neurons first extend a dendrite and express the axonal growth protein GAP-43 (Verhaagen, J. *et al.*, 1989; Meiri, K. F. *et al.*, 1991; Schwob, J. E. *et al.*, 1995). Within about a week of their birth the neurons have elaborated cilia, turned off GAP-43, and turned on OMP (Miragall, F. and Monti Graziadei, G. A., 1982; Schwob, J. E. *et al.*, 1995). OR expression lags the onset of neuronal differentiation by a few days, but is seen before OMP is expressed (Iwema, C. L. and Schwob, J. E., 2003).

Of the two cell types in the basal zone of the OE, tracing of cell lineage by use of a replication-incompetent, retrovirally derived vector (RRVV) or by dye injection into basal cells both show that neurons derive from GBCs (Schwartz Levey, M. *et al.*, 1992; Caggiano, M. *et al.*, 1994; Schwob, J. E. *et al.*, 1994a). The lineage analyses correspond with the demonstration that there is a parallel increase in GBC proliferation and neuronal production occasioned by damage to the ON and OB (Schwartz Levey, M. *et al.*, 1991). Subsequent analyses of the sequential expression of TFs that activate neurogenesis (i.e., Mash1, Ngn1, and NeuroD1) by GBCs during development and after lesion, provide a further indication that GBCs are the proximate precursors of neurons in the OE (Guillemot, F. *et al.*, 1993; Gordon, M. K. *et al.*, 1995; Cau, E. *et al.*, 1997; 2002; Manglapus, G. L. *et al.*, 2004).

Does GBC proliferation and neuron production persist throughout life? In most humans and experimental animals, the answer is yes. However, in humans, biopsies do show areas of epithelium that remain olfactory in character (i.e., containing microvillar-capped Sus cells) but are aneuronal, suggesting that the neurogenic capacity of the olfactory stem and progenitor cells can be exhausted (Holbrook, E. L. *et al.*, 2005). Interestingly, the same neurogenic exhaustion is observed in rodents in which an oncogene is expressed under the control of the OMP promoter (Largent, B. L. *et al.*, 1993); as the expression of an oncogene in a terminally differentiated cell often initiates programmed cell death (Al-Ubaidi, M. R. *et al.*, 1997; Feddersen, R. M. *et al.*, 1997), neuronal turnover may be grossly accelerated, and from an early stage, in these transgenic mice.

At the time the original data were obtained indicating adult neurogenesis, only the olfactory neurons were believed to be subject to replacement. Subsequently, the birth of other neuronal populations in adults, including the interneurons of the OB, was demonstrated elsewhere in the adult nervous system (Kaplan, M. S. and Hinds, J. W., 1977; Kaplan, M. S. *et al.*, 1985; Lois, C. and Alvarez-Buylla, A., 1993; 1994; Menezes, J. R. *et al.*, 1995). Nonetheless, the rate of production as a percentage of the established population appears higher in the OE than anywhere else, and more subject to regulation on the basis of need.

The original observations on basal cell proliferation were interpreted as an indication that sensory neurons within the OE had a fixed, finite lifespan, like epithelial cells of gut or skin (Moulton, D. G. *et al.*, 1970; Graziadei, P. P. and Metcalf, J. F., 1971; Graziadei, P. P., 1973; Moulton, D. G., 1974; 1975; Graziadei, P. P. C. and Monti Graziadei, G. A., 1978; Graziadei, P. P. and Monti Graziadei, G. A., 1979). Moreover, the rate of proliferation was used as a means of estimating that the neurons lived for about a month, on average. However, the pulse–chase data cannot be interpreted as providing evidence for the notion that the turnover of mature, synaptically connected olfactory sensory neurons (OSNs) occurs automatically at the end of a fixed (relatively) brief lifespan. Neither the original nor subsequent data preclude the notion that turnover might take place within a reserve population of unconnected, relatively immature neurons. In fact, neurons undergoing programmed cell death or apoptosis are found within both the immature and OMP-positive population in the normal adult OE (Holcomb, J. D. *et al.*, 1995; Deckner, M. L. *et al.*, 1997); in that vein it is also important to note that the onset of OMP expression is NOT by itself an indication of synaptic connectivity. Subsequent demonstrations have also weakened the association between ongoing neurogenesis and any prescribed replacement of mature neurons in the protected environment experienced by laboratory-housed animals. For example, the lifespan of newly born OSNs from animals that are in a pathogen-free, filtered air environment may be as long as a year (Hinds, J. W. *et al.*, 1984). Moreover, when the preexisting neurons are tagged by retrograde transport of a stable marker from the bulb, the labeled OSNs persist for a period of time that is substantially longer than a month (Mackay-Sim, A. and Kittel, P. W., 1991b); unfortunately, these data do not permit a determination of whether lifespan is indefinite once a neuron becomes established. Finally, a mechanism exists that allows the system to regulate survival of newly generated neurons on the basis of their connectivity status, which would be required if lifespan is not inherently limited. In more specific

terms, OSNs exhibit a trophic dependency on the OB for their prolonged survival, such that lifespan is abbreviated for neurons born in the absence of the bulb (Monti Graziadei, G. A., 1983; Biffo, S. *et al.*, 1992; Schwob, J. E. *et al.*, 1992; Carr, V. M. and Farbman, A. I., 1993; Mackay-Sim, A. and Chuah, M. L., 2000). Trophic dependency is a means by which the system might eliminate those newly born neurons that fail to make any or the appropriate synaptic connections (Purves, D., 1988). Thereby the size of the sensory population may be regulated in accordance with the status of the target, which might, itself, be modified by sensory activity and odorant saliency, among other influences. Given these provisos, it is fair to say that the definitive experiments have not yet been done that would allow us to determine the lifespan of preexisting sensory neurons in the laboratory environment or any other milieu.

4.34.4 Response to Injury – Reconstitution of the Epithelium

The primary olfactory system has been subjected to three general forms of experimental injury: direct toxic injury to the OE; traumatic injury to the ON, OB, or both; and viral infection following intranasal inoculation.

4.34.4.1 Toxic Injury to the Olfactory Epithelium

Damage to the OE ensues in some cases by direct contact of a toxin with the epithelium; the two most widely used of these are zinc-containing salts, in particular zinc sulfate, delivered by intranasal infusion (Smith, C. G., 1938; Schultz, E. W., 1960; Matulionis, D. H., 1975; 1976; Harding, J. W. *et al.*, 1978; Cancalon, P., 1982; Burd, G. D., 1993), and MeBr, for which passive inhalation is the route of exposure (Hurtt, M. E. *et al.*, 1987; 1988; Schwob, J. E. *et al.*, 1995). In other cases, some toxins damage or destroy the OE after systemic administration; among these are 3-methyl indole (skatol), dichlobenil, and methimazole (Schwob, J. E. *et al.*, 1994b; Brittebo, E. B., 1995; Genter, M. B. *et al.*, 1995; 1996; Slotnick, B. *et al.*, 2001). The mechanism by which zinc sulfate causes relatively selective damage to the OE after intranasal administration is not known in any detail, although speculation has centered on the protein-coagulative properties of the salt (Schultz, E. W. and Gebhardt, S. P., 1942). MeBr, which effect is absolutely selective for damage to the OE within the nose, is apparently converted to an active free radical toxin via biotransformation enzymes in the epithelium, most likely one or more members of the cytochrome P450 family (Reed, C. J. *et al.*, 1995). Other features of the olfactory toxicity of MeBr that reflect the need for activation include the relative insensitivity of younger animals, the strain dependence of efficacy in mice, and the absolute refractoriness to lesion under circumstances when the biotransformation systems are substantially diminished relative to normal (e.g., the OE cannot be lesioned again by a subsequent exposure to toxin during the immediate post-MeBr lesion period when cytochrome P450 enzymes are far below normal levels) (Schwob, J. E., unpublished results). Other systemically acting toxins, for example, skatol, may also exert their effect after enzymatic activation by that system.

The immediate effects of lesion have been studied in some detail for both zinc sulfate and MeBr. However, much of the zinc literature predates the availability and use of cell-type-specific reagents to study reconstitution of the OE. Accordingly, the timing and events of epithelial recovery is better known from the studies of MeBr lesions published more recently (Figure 1(b)). In virtually all cases where a direct comparison can be made, the findings with MeBr are highly analogous to those seen following zinc sulfate.

Inhalation of the toxin in MeBr-sensitive animals leads to a rapid loss (sloughing) of all neurons and supporting cells in over 95% of the OE within 24 h, and damage to those populations in the remainder of the tissue (Schwob, J. E. *et al.*, 1995). In addition, the Bowman's glands in the lamina propria are damaged but incompletely. The GBC, HBC, and duct cell populations also sustain some loss. In particular, HBCs disappear from the ventral OE in lesioned rats (but not mice) by the third day after exposure. In contrast, agents like methimazole take several days to produce maximal damage, which makes study of the initial events during epithelial regeneration difficult due to the concurrence of cell loss and replacement (Brittebo, E. B., 1995; Genter, M. B. *et al.*, 1995; Bergstrom, U. *et al.*, 2003). Within 2 days after MeBr, the remaining cells undergo a quick upsurge in proliferation. The first neurons to reappear do so at about 4 days after lesion, and then mature, that is, express OMP, around the middle of the second week after lesion, at roughly the same time as the first returning axons reinnervate glomeruli in the bulb. Likewise, the Sus cells begin to reappear within a few days, and reform a distinct

layer at the apex of the epithelium by 10 days after lesion. By 6–8 weeks after MeBr, the majority of the OE has stabilized to a state that is indistinguishable from normal, as judged by the rate of GBC proliferation, the relative proportion of immature-to-mature OSNs, and the restoration of normal or near-normal levels of expression of cytochrome P450 enzymes (Schwob, J. E. *et al.*, 1995).

Depending on its severity, the initial lesion may preclude the recovery of the lesioned epithelium as olfactory, and the events underlying failure may model the pathophysiology of some forms of human olfactory dysfunction (Schwob, J. E. *et al.*, 1994b; Jang, W. *et al.*, 2003). For example, MeBr lesion can be enhanced such that all GBCs are eliminated from patches of the OE; the GBC-depleted areas reconstitute as respiratory epithelium (a form of metaplasia) (Jang, W. *et al.*, 2003). The same kind of metaplasia, is observed following zinc sulfate infusion or a combination of skatol injection and MeBr inhalation, and is often more extensive than with MeBr (Smith, C. G., 1938; Burd, G. D., 1993; Schwob, J. E. *et al.*, 1994b).

4.34.4.2 Epithelial Response to Nerve Transection or Olfactory Bulb Ablation

In contrast to the effects of and response to directly acting toxins, cell loss following nerve or bulb injury is limited to the OSNs. Nerve transection or bulb ablation causes retrograde degeneration of the neurons via a caspase-mediated process of programmed cell death (or apoptosis) within the space of a few days (Harding, J. *et al.*, 1977; Monti Graziadei, G. A. and Graziadei, P. P., 1979; Simmons, P. A. *et al.*, 1981; Costanzo, R. M. and Graziadei, P. P., 1983; Monti Graziadei, G. A., 1983; Verhaagen, J. *et al.*, 1990; Schwartz Levey, M. *et al.*, 1991; Carr, V. M. and Farbman, A. I., 1992; Gordon, M. K. *et al.*, 1995; Holcomb, J. D. *et al.*, 1995; Calof, A. L. *et al.*, 1998; Cowan, C. M. *et al.*, 2001; Cowan, C. M. and Roskams, A. J., 2002). Neuronal loss causes the upregulation of GBC proliferation only; the feedback inhibition from OSNs onto the mitotic activity of GBCs in the normal OE, which is apparently mediated by bone morphogenetic proteins (BMPs) 4 and 7 and by growth differentiation factor (GDF)11, is released (Gordon, M. K. *et al.*, 1995; Shou, J. *et al.*, 1999; 2000; Wu, H. H. *et al.*, 2003). Moreover, cytokines, including leukemia inhibitory factor (LIF), that are released by infiltrating macrophages may also play a role in the activation of GBCs in response to neuronal degeneration (Nan, B. *et al.*, 2001; Bauer, S. *et al.*, 2003). As a consequence, expansive proliferation occurs within the GBC population, followed by an increased rate of neuronal production (Figure 1(a)) (Monti Graziadei, G. A. and Graziadei, P. P., 1979; Schwartz Levey, M. *et al.*, 1991). Basal cell proliferation and neuron production remains elevated over the long term in bulb-ablated animals, and perhaps nerve transected ones as well (Schwob, J. E. *et al.*, 1992). Following ablation, the abbreviated lifespan caused by the loss of trophic support from the bulb is such that the neuronal population is dominated by immature OSNs, instead of mature ones, while the size of the population always remains less than that of normal OE, despite accelerated neurogenesis (Verhaagen, J. *et al.*, 1990; Biffo, S. *et al.*, 1992; Schwob, J. E. *et al.*, 1992; Konzelmann, S. *et al.*, 1998). In contrast, nerve transection permits substantial though incomplete reinnervation of the bulb as well as some mistargeting; as a consequence, the population of OSNs recovers more fully toward normal than after bulb ablation (Monti Graziadei, G. A. and Graziadei, P. P., 1979; Graziadei, P. P. and Monti Graziadei, G. A., 1980; Costanzo, R. M., 1984; 1985; Koster, N. L. and Costanzo, R. M., 1996; Yee, K. K. and Costanzo, R. M., 1998; Costanzo, R. M., 2000; Christensen, M. D. *et al.*, 2001; Costanzo, R. M., 2005).

Other cell populations in the OE show a response to the lesion, although it is not mitotic. For example, the levels of cytochrome P450 enzymes decrease in Sus cells (Walters, E. *et al.*, 1992). In addition, Sus cells become active phagocytes (Suzuki, Y. *et al.*, 1995; 1996).

4.34.4.3 Effects of Viral Infection on the Olfactory Epithelium

The damage to the epithelium caused by viral infection is a much more frequent antecedent of olfactory dysfunction in humans than either toxin exposure or head trauma (for which nerve transection and/or bulb ablation is generally held to be analogous) (Doty, R. L., 1979; Moran, D. T. *et al.* 1992; Seiden, A. M., 2004; Holbrook, E. H. and Leopold, D. A., 2006). Biopsies of the human mucosa and specimens taken at autopsy indicate that the replacement of olfactory by respiratory epithelium is not a rare event in the human mucosa (Nakashima, T. *et al.*, 1984; Nakashima, T. *et al.*, 1985). Indeed, loss of neurogenic capacity due to respiratory metaplasia or stem cell exhaustion can become complete, leading to anaxonic, fibrotic ON fascicles (Holbrook, E. H. *et al.*, 2005). (Collagen

deposition and fibrosis of ON fascicles is also observed in Macaque, but not in rodents (Graziadei, P. P. *et al.*, 1980).) Experimental models that duplicate the changes observed following viral infections in humans are rare and mechanistically obscure. However, it is worth noting that certain neurotropic viruses can gain entry to the CNS by infection of OSNs and anterograde transport to, and release from, the terminals of the ON, without killing the infected sensory neurons (Barthold, S. W., 1988; Schwob, J. E. *et al.*, 2001). To the extent that they cause downstream damage to the OB, the OE can come to resemble that which is harvested from bulbectomized animals.

4.34.5 Stem and Progenitor Cells of the Adult Olfactory Epithelium

The unique capacity of the OE to reconstitute after injury, for example, following inhalation of MeBr, reflects and requires the persistence of one or more types of neurocompetent stem cells, from which spring the downstream progenitors that eventually give rise to the various missing cell types. Of necessity, neurocompetent stem cells must be found within one or more of the three cell types that are spared following MeBr lesion: GBCs, HBCs, or duct cells. Of equal necessity, candidate olfactory stems must satisfy a certain operational definition that emerged from studies of cellular renewal in tissues like skin and gut, as follows. Tissue stem cells are totipotent (with respect to the tissue in question), infinitely self-renewing, and mitotically quiescent when the tissue is undamaged (Hall, P. A. and Watt, F. M., 1989; Rao, M. S., 1999; Watt, F. M., 2001; Alonso, L. and Fuchs, E., 2003; Pevny, L. and Rao, M. S., 2003). In the conventional model, progenitors of progressively more limited differentiative potency or capacity for self-renewal or both arise from and are downstream of the stems. Most investigators identify a kind of lineage-restricted progenitor that retains a capacity for expansive proliferation and call it a transit-amplifying (TA) cell (Potten, C. S. and Loeffler, M., 1990; Potten, C. S., 1998; Watt, F. M., 2001; Alonso, L. and Fuchs, E., 2003). Further downstream are the cells that are charged with giving rise to the differentiated tissue elements, and are called immediate precursors, for example, immediate neuronal precursors (INPs) in the OE.

4.34.5.1 Some Global Basal Cells Are Multipotent Progenitors

Our current understanding of the players and processes underlying cellular renewal in the olfactory system is based on RRVV lineage tracing experiments (Huard, J. M. *et al.*, 1998), *in vivo* transplantation studies using purified populations of cells (Goldstein, B. J. *et al.*, 1998; Chen, X. *et al.*, 2004), on gene expression analysis following lesion or in the embryonic placode (Manglapus, G. L. *et al.*, 2004), on the consequences of gene mutation (Cau, E. *et al.*, 1997; Fisher, A. and Caudy, M., 1998; Cau, E. *et al.*, 2000; 2002; Murray, R. C. *et al.*, 2003), and on *in vitro* studies (Shou, J. *et al.*, 1999; Satoh, M. and Yoshida, T., 2000; Carter, L. A. *et al.*, 2004). All of these data indicate that some cells within the population of GBCs are capable of a broad multipotency in the context of the MeBr-lesioned OE; hence, the GBCs may ultimately be responsible for the reconstitution of much of the OE after lesion and not merely the neuronal population (Figures 1(b) and 2). In aggregate, GBCs give rise to GBCs (a form of self-renewal), neurons, Sus cells, microvillar cells, HBCs, duct and gland cells, and even respiratory epithelial cells. Not all cell types are found in all clones – individual clones from transplanted GBCs or from RRVV-labeled progenitors may contain multiple cell types, or may consist of neurons or Sus cells alone – but there is a rough correlation between large clones, a greater number of cell types, and the presence of GBCs (i.e., a form of self-renewal). Hence, the differentiative potency of GBCs in the MeBr-lesioned OE seems to be as broad as that of the olfactory placodal cells, which are the embryonic precursors for all of the nasal lining. It is important to note that some multipotent cells present in the normal epithelium are active in the mitotic cycle as shown by infectability with RRVV *ex vivo* prior to transplantation into a host. Thus, the decision between neuropotency and multipotency is one that is made on a continuous basis in the normal OE.

4.34.5.2 Globose Basal Cells Are the Only Population for Which Functional Heterogeneity Has Been Demonstrated

Among the GBC population of both embryonic and adult OE are subsets that can be distinguished one from the next on the basis of their expression of TFs of the bHLH family of TFs, which in turn appear to correlate with difference in their potency as precursors (Cau, E. *et al.*, 1997; 2000; 2002; Manglapus, G. L. *et al.*, 2004). In particular, observations on mice

bearing engineered mutations of the bHLH family members as well as analyses of TF expression in developing and regenerating OE have lead to a conceptualization of flow through the GBC population that acknowledges the diversity of precursor types (Figure 2). At the origin are the stem cells and broadly multipotent GBCs ($GBCs_{MPP}$) capable of giving rise to all cell types present in the OE as well as the respiratory epithelial cells normally found elsewhere in the nasal lining; it is likely that some, possibly most, broadly potent GBCs are not stems. Downstream of them are cells en route to terminally differentiated neurons only; among the downstream elements committed to neurogenesis are transit-amplifying GBCs ($GBCs_{TA}$) and INPs. Based on a comparison with TF markers, GBCs of all three functional types – MPPs, TAs, and INPs – are actively proliferating in the normal OE. In the usual formulation, the cellular flow in this model is depicted as unidirectional, and from less committed to more (Figure 2). However, as a greater appreciation for the plasticity of stems and progenitors has emerged, a case can be made for reevaluating the conventional notion of unidirectional flow.

Some of the molecular correlates of multipotency among the GBCs can be adduced (Figure 2). $GBCs_{MPP}$ express antigens that are recognized by MAbs GBC-1, GBC-2, and GBC-3 (the latter recognizing a carbohydrate moiety on iLRP) based on the comparison of timing of expression after MeBr lesion, the outcome of RRVV infection, and the use of these antibodies for fluorescence-activated cell sorter (FACS) (Goldstein, B. J. and Schwob, J. E., 1996; Goldstein, B. J. *et al.*, 1997; Huard, J. M. *et al.*, 1998; Jang, W. *et al.*, 2003; Chen, X. *et al.*, 2004; Jang, W. *et al.*, 2007). However, none of the three differentiates GBC_{MPP} from GBCs committed to making neurons selectively.

The timing of bHLH TF expression relative to recovery of the OE after MeBr lesion (Manglapus, G. L. *et al.*, 2004) and the pattern of gene expression and epithelial composition in Mash1 (−/−) mutant animals, (Guillemot, F. *et al.*, 1993; Cau, E. *et al.*, 1997) help narrow and contrast the molecular profile of the MPPs and other progenitors. These data suggest that the $GBCs_{MPP}$ do not express Mash1, nor the TFs NeuroD and Ngn1, which are expressed after Mash1 in the embryonic and in the regenerating OE. $GBCs_{TA}$ that are downstream of the $GBCs_{MPP}$ and

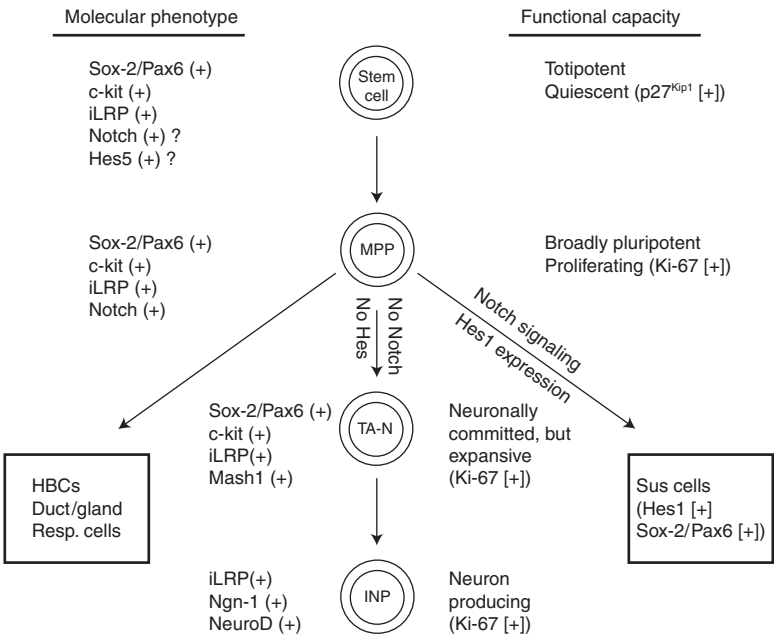

Figure 2 Functional classification and categorization of globose basal cells (GBCs) correlates with molecular phenotype. Central to differences in progenitor capacity seem to be members of the basic helix–loop–helix family of transcription factors (Hes, Mash, Ngn, and NeuroD) as well as the transcription factors Sox-2 and Pax6. For the latter factors, the pattern of expression in normal epithelium and during recovery from methyl bromide (MeBr) lesion suggests that they repress neuronal differentiation, which they do in other parts of the nervous system, a function which is required up to the final progenitor cell stage in the epithelium.

committed to a neuronal fate express Mash1, based on an analysis of Mash1 mutant mice and of the timing of its expression relative to lesion and embryonic development. Other GBCS that are further downstream and act as immediate neuronal precursors or producers ($GBCs_{INP}$) express NeuroD and/or Ngn1. All three functional types are present and mitotically active in the normal OE.

The same kind of analysis eliminates the bHLH TF Hes1 as a marker for, or critical to, the function of $GBCs_{MPP}$. Although *Hes1* expression appears in a substantial number of GBCs within 1 day of MeBr lesion, quickly thereafter the *Hes1* (+) cells shift apicalward and differentiate into Sus cells (Manglapus, G. L. *et al.*, 2004). The differentiation of *Hes1* (+) GBCs ($GBCs_{Sus}$) into Sus cells fits with the specific expression of Hes1 by Sus cells in OE of normal or bulbectomized animals; in these settings the GBC population makes only neurons. Thus, *Hes1* expression by GBCs does not indicate multipotency *per se* but seems to convey commitment to a Sus cell lineage. Parenthetically, *Hes1* is not needed to make Sus cells when expression of the *Mash1* gene is eliminated by genetic recombination, as supporting cells of the *Mash1* mutant mice do not express *Hes1* (Cau, E. *et al.*, 2000). These data fit with a demonstrated role for Hes1 protein, namely the suppression of *Mash1* expression; in the absence of *Mash1*, no such repression is needed.

However, the expression patterns of the TFs SOX-2 and Pax6 – high-mobility group (HMG) and paired domain TFs, respectively, that frequently cooperate in regulating gene transcription – indicate that $GBCs_{MPP}$ can be identified as GBCs that express these two TFs, and are not marked by expression of Mash1, or HBC, or Sus cell markers (cell types which also express the two TFs). In more specific terms, all GBCs in the OE from the immediate postlesion period express SOX-2 and Pax6 (Guo, Z. *et al.*, 2005a; 2005b); at this time the vast majority of GBCs are proliferating and either multipotent or making Sus cells. In their joint expression of SOX-2 and Pax6, $GBCs_{MPP}$ resemble the cells of the olfactory placode/pit (Grindley, J. C. *et al.*, 1995), which are the embryonic founders for the OE (as well as all other parts of the lining of the nasal cavity). Furthermore, stem cells of the embryonic CNS also seem to express both SOX-2 and Pax6 (Gotz, M. *et al.*, 1998; Marquardt, T. *et al.*, 2001; Chi, N. and Epstein, J. A., 2002; Avilion, A. A. *et al.*, 2003; Graham, V. *et al.*, 2003; Ellis, P. *et al.*, 2004; Brazel, C. Y. *et al.*, 2005; Englund, C. *et al.*, 2005).

In the final analysis, despite satisfying the multipotency criterion, it is unlikely that the actively proliferating $GBCs_{MPP}$ are stems, but rather they are most likely downstream of the bona fide stem cells.

4.34.5.3 Quiescent Globose Basal Cells

Among the GBC population are ones that express another characteristic of stem cells, namely prolonged mitotic quiescence. Hinds (Hinds, J. W. *et al.*, 1984) and then MacKay-Sim (Mackay-Sim, A. and Kittel, P., 1991a) recognized a population of basal cells that retained thymidine label for a prolonged period of time, but did not determine whether the label-retaining basal cells were HBCs or GBCs or both. Recent work extends the earlier observations and shows that some GBCs in normal OE express the cyclin-dependent kinase inhibitor (CDKI) $p27^{Kip1}$, and some retain BrdU label for periods of a month or more (Chen, X., 2003). MeBr lesion causes them to reenter the mitotic cycle with the consequence that p27 (+) cells disappear during the ramping up of proliferation during the acute postlesion period. Beginning 4 days after lesion, some GBCs return to quiescence; p27 (+) GBCs reappear and BrdU label begins to be retained by some GBCs. The kinetic characteristics of this population are like those of stems in other tissues, for example, the cornea.

4.34.5.4 Are Some Cells Among the Globose Basal Cells Tissue Stem Cells of the Olfactory Epithelium?

Of the characteristics of stem cells, some GBCs satisfy the totipotency criterion (with regard to the OE), including regeneration of GBCs, which implies at least a limited capacity for self-renewal. The data also show that some GBCs are quiescent for a long period of time. Finally, loss of GBCs results in a failure of neurogenesis and respiratory metaplasia. All of these are necessary characteristics for identifying stem cells, but are not sufficient. Unfortunately, we do not yet have the kinds of assays that allow us to define extensive self-renewal, as has been done for CNS stem cells, among others. Nonetheless, the findings gathered to date are highly suggestive that mitotically quiescent, SOX-2/Pax6 (+) GBCs are true tissue stem cells.

4.34.5.5 Progenitor Capacity of Other Epithelial Cell Types

The other stem cell candidates in the OE are the HBCs and duct/gland cells (Mulvaney, B. D. and Heist, H. E., 1971; Graziadei, P. P. and Monti Graziadei, G. A., 1979). The duct/gland cells do not seem to have any degree of neuropotency. When MeBr exposure is adjusted to cause a more severe lesion of the OE destroying all of the HBCs and GBCs in an area, the damaged OE is replaced by respiratory epithelium, even though gland cells proliferate and erupt superficial to the basal lamina (Jang, W. *et al.*, 2003). Nor do transplanted duct cells do anything other than give rise to Sus/duct cells (Chen, X. *et al.*, 2004). Although there is some evidence for expression of neuronal markers by HBCs *in vitro* (Satoh, M. and Yoshida, T., 2000; Carter, L. A. *et al.*, 2004), transplantation is not effective in generating other cell types. In the lesioned OE of mice, the HBCs do not engraft (perhaps because they are preserved and proliferate throughout OE in contrast to their disappearance from ventral OE as a consequence of toxin exposure in rats) (Chen, X. *et al.*, 2004). In MeBr-lesioned rats, HBCs labeled by the uptake of fluorescent latex microspheres (beads) do engraft but do not seem to do anything except make other HBCs. However, morphological analysis, and rare RRVV-labeled clones suggest that the HBCs can generate Sus cells as well as themselves in the context of the MeBr-lesioned OE. By no means can the extant *in vivo* data be considered definitive. Thus, we cannot yet discard the hypothesis that neurocompetent stem cells might also be found among the HBCs.

4.34.6 Reinervation of the Olfactory Bulb

Anecdotal reports of functional recovery in humans following either epithelial lesion or nerve transection imply some degree of reinnervation of the bulb by the newly born neurons of the reconstituted epithelium. In the context of the piecemeal turnover of the OSN population during normal life, that nascent innervation of the bulb by newly born neurons is remarkably precise as shown intuitively by the perceptual stability of olfaction in humans and the maintenance of precise connectivity in lab animals, both of which are the norm in adult life (Figure 3(a)). What then of the wholesale loss and reformation of the axonal projection onto the bulb following peripheral lesion? What do axon growth and synaptogenesis in that setting tell us of mechanisms regulating innervation of the bulb and their action following lesion?

4.34.6.1 Normal Organization of the Axonal Projection from the Olfactory Epithelium onto the Olfactory Bulb

The projection of the OE onto the OB is organized at three levels: At its coarsest, the organization of the projection is rhinotopic, in which there is a rough correspondence between regions of the OE and the part of the glomerular layer that they target: dorsal OE to dorsomedial OB, lateral OE to lateral and dorsolateral OB, etc. (Astic, L. and Saucier, D., 1986; Saucier, D. and Astic, L., 1986; Astic, L. *et al.*, 1987; Schoenfeld, T. A. *et al.*, 1994). The boundaries between one target region in the bulb and the next are probably not sharp. The graded, shifting projection at the boundary is demonstrated by the distribution of axons from biochemically distinct populations of neurons, that is, ventrolateral, OCAM/mamFasII (+) versus dorsomedial, OCAM/mamFasII (−), which are sharply delimited in the OE but whose axons intermingle in selected glomeruli at the margins between groups of wholly positive or wholly negative glomeruli (Mori, K. *et al.*, 1985; Schwob, J. E. and Gottlieb, D. I., 1986). As a consequence, the axon terminal field of the neuropil of some of these border glomeruli exhibit intermediate levels of immunohistochemical staining with the anti-OCAM/mamFasII MAb RB-8.

The next more precise level of the projection – that is, onto groups of glomeruli – reflects the identity of the OR expressed by the neurons in question. Thus, neurons in the unlesioned adult OE expressing a particular OR, for example, as shown for P2, OR37A, and OR37C, will target one or two glomeruli within a roughly 250 μm-diameter patch consisting of about 30 or so potential target glomeruli (Strotmann, J. *et al.*, 2000; Schaefer, M. L. *et al.*, 2001). The target patch is found in a consistent location from animal to animal relative to defined landmarks of the bulb. For convenience, that level of specificity can be termed receptotopic. Within that patch, location is inconsistent; for example, the glomerulus innervated by OR37A is found in all possible relations to the one innervated by OR37C in the same patch: anterior, posterior, medial, or lateral to the OR37C glomerulus. Thus, a patch is shared as a target by multiple different kinds of OR-defined sensory neurons.

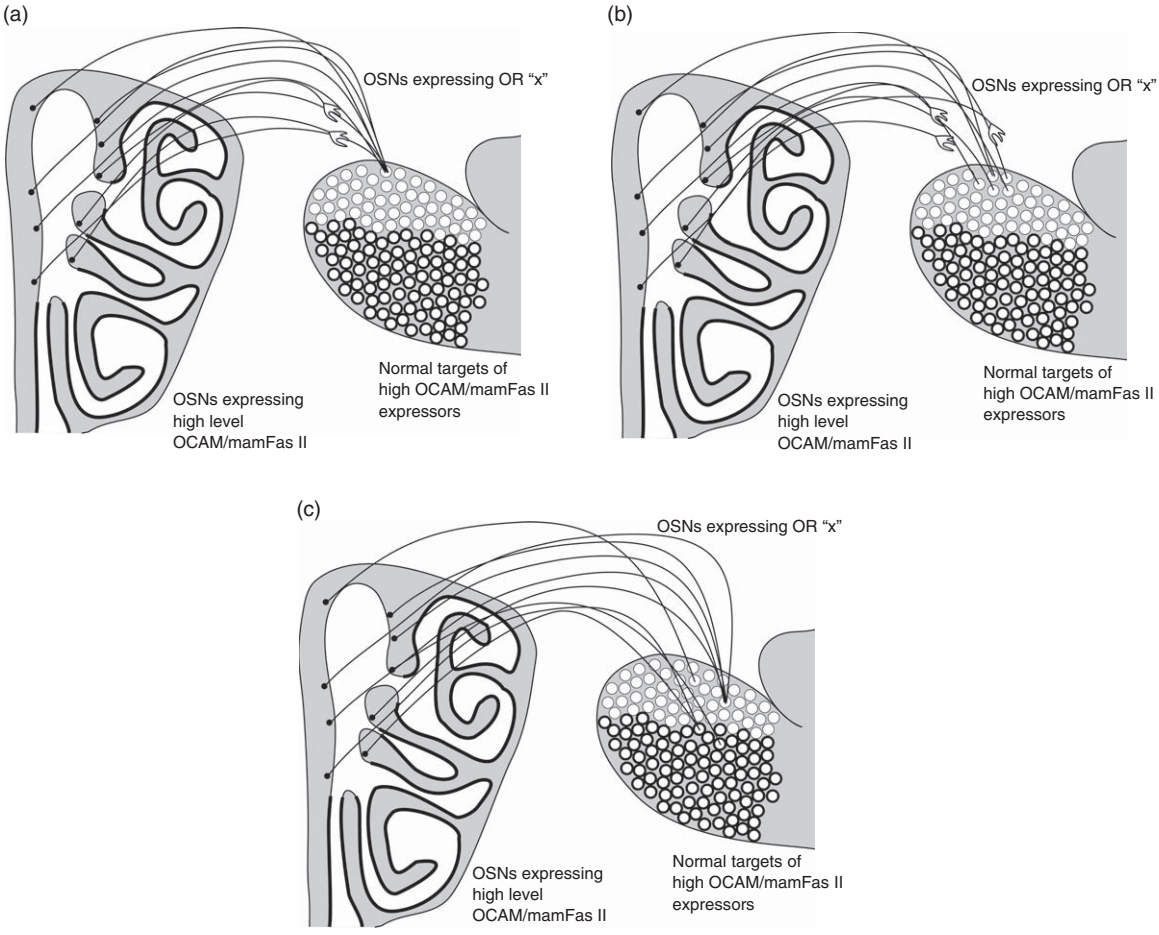

Figure 3 The accuracy of reinnervation of the olfactory bulb by newly born sensory neurons depends on the extent of neuron loss, and on the occurrence of damage to the olfactory nerve. (a) Glomerular targeting in the peripheral olfactory projection of normal animals, i.e., during piecemeal turnover of the neuronal population is highly accurate, and maintains preexisting glomerulotopy. The same outcome is observed when one odorant receptor (OR)-defined group of sensory neurons is ablated and then regenerated. The thick dark line in the cartoon of the nose on the right indicates the part of the olfactory epithelium in which neurons (OSNs) express OCAM/mamFas II at a high level. The glomeruli outlined with the thick dark line represent the normal targets for the high OCAM/mamFas II-expressing neurons. (b) Like the normal, following wholesale neuronal turnover caused by exposure to methyl bromide (MeBr), rhinotopy is restored, and the newly born neurons target approximately the same area within the glomerular sheet, reestablishing receptotopy. However, in contrast with normal, no longer do all of the group of OR-defined neurons converge onto a single glomerulus. (c) Following transection of the olfactory nerve, rhinotopy is distorted – as indicated by the low OCAM/mamFas II-expressing OSNs that innervate what are normally targets for high expressors – and neither targeting to the usual region of the glomerular layer nor convergence onto a single glomerulus is restored.

At its most precise, the projection onto the normal OB is characterized by the convergence of like fibers, that is, those expressing the same OR, most often onto a single glomerulus within the patch, which they seem to fill homogeneously and from which other OR-defined axonal types are apparently excluded (Mombaerts, P. *et al.*, 1996; Wang, F. *et al.*, 1998; Potter, S. M. *et al.*, 2001; Treloar, H. B. *et al.*, 2002; Feinstein, P. and Mombaerts, P., 2004; Feinstein, P. *et al.*, 2004). Studies during the normal development of the projection suggest that unlike fibers intermingle initially within the common patch, but then the active coalescence of like fibers and their progressive segregation from unlike fibers comes to account for both the remarkable convergence of like fibers and the final position of the target glomerulus within the patch (Conzelmann, S. *et al.*, 2001). For convenience, the level of specificity implied by the convergence of like fibers onto a single glomerulus can be termed glomerulotopic.

4.34.6.2 Organization of the Projection Following Recovery from Injury to the Periphery

To what extent are the three levels of specificity that characterize the projection from OE onto OB in normal animals restored following reconstitution of the periphery and reinnervation of the bulb? Two settings may be contrasted: one in which the sensory neuron population undergoes wholesale turnover, for example, the cycle of destruction and reconstitution initiated by a general olfactotoxic agent (Schwob, J. E. *et al.*, 1999; Iwema, C. L. and Schwob, J. E., 2001; St John, J. A. and Key, B., 2003; Carr, V. M. *et al.*, 2004); the second, in which a specific OR-defined set of neurons has been eliminated through genetic means, for example, selective killing of P2 neurons via P2- and tetracycline-regulated expression of diptheria toxin (Gogos, J. A. *et al.*, 2000). In the case of MeBr lesion, the newly born neurons begin to fill the glomerular layer by 7 days after lesion, begin to reenter glomeruli near the end of the second week, fill them by the end of the third week and have stabilized by the end of the eighth week after lesion (Schwob, J. E. *et al.*, 1999).

The first issue that must be addressed following wholesale turnover of the sensory neuronal population is the fidelity with which the number and distribution of the various OR-defined classes of OSNs is restored across the epithelial sheet. Recent experiments utilized unilateral naris closure during the period of MeBr exposure (which has the effect of protecting the closed side from the effects of the gas almost completely), long postlesion survivals, and *in situ* hybridization (ISH) using multiple OR probes to compare lesioned-recovered and unlesioned OE (Iwema, C. L. *et al.*, 2004). Remarkably, the spatial patterning of OR expression was equivalent on the two sides, and the numbers of neurons labeled with the probe were also very similar in the lesioned-recovered epithelium as compared to the unlesioned. The extent of recovery is all the more striking given the partial depletion of the GBC population by the lesion and the degree of respiratory metaplasia in the ventrolateral areas of the epithelium. *A priori*, one can imagine two mechanisms by which position across the epithelial sheet comes to constrain OR expression: either the stem cells have a memory of place which is responsible for spatially imposed restrictions as the neurons are regenerated, or environmental cues derived from the lamina propria drive OR selection, at least after lesion from which effects the lamina cells would be protected. Of the two, the damage to the GBC population, which almost certainly must vary from animal to animal with respect to the OR-defined boundaries, suggests that cues external to the stem–progenitor-differentiating neuron hold sway and drive OR choice.

Despite the impressive degree to which the periphery is restored, a severe epithelial lesion is accompanied by targeting errors during reinnervation of the bulb. Projection errors can be detected at a very gross level as a reduction in the overall extent of reinnervation. Thus, when the severity of the initial lesion is enhanced, such that the recovery of the lesioned epithelium is incomplete and reduced to about four-fifths of its normal surface area, glomeruli at and near the posterior margins of the glomerular sheet remain denervated permanently (Schwob, J. E. *et al.*, 1999). Given that the reduction in the innervating population is not selective to a particular OR-defined type, the failure to reinnervate the posterior bulb indicates errors in receptotopic targeting. Interestingly, that failure in the anteroposterior dimension does not seem to interfere with the establishment of rhinotopic territories. Retrograde tract tracing experiments following selective labeling of the dorsomedial versus ventrolateral glomerular layer suggest little or no breakdown in the gross rhinotopic targeting onto the bulb (Schwob and Hamlin, unpublished results). That return to normalcy is confirmed by using the OCAM/mamFasII-specific MAb RB-8 to define the respective projections of the corresponding epithelial territories onto the bulb of rats following recovery from unilateral epithelial lesion.

The analyses of reinnervation by specific types of OSNs confirm that interpretation. Following peripheral lesion of P2-IRES-tauLacZ strain of transgenic mice with MeBr or with dichlobenil, the P2 fibers no longer converge to a single glomerulus on each surface of the bulb (Figure 3(b)) (Iwema, C. L. and Schwob, J. E., 2001; St. John, J. A. and Key, B., 2003). Instead, multiple glomeruli in the vicinity of the original one become innervated, but the P2 fibers in them are now only one part of a mix of axons of different types, in other words, the P2 fibers are only some of the OMP (+) axons innervating those glomeruli. Indeed, the P2 fibers tend to be plastered at the edges of the glomerular neuropil where they are more densely clustered than usual. The projection of other neuron types onto the bulb is also degraded relative to the unlesioned projection; like P2 neurons they come to innervate more than the normal number of glomeruli (Carr, V. M. *et al.*, 2004). Thus, the

capacity to target a specific region or target patch within the glomerular layer is maintained, at least at anterior levels of the bulb, but no longer do the fibers converge properly and selectively.

In contrast, the projection to the P2 glomeruli is restored to its normal uniglomerular pattern following selective ablation by genetic means of all but a very small percentage of the extant P2 neurons, and their subsequent regeneration (Gogos, J. A. *et al.*, 2000). However, the environment experienced by the nascent P2 axons is quite different between global lesions and the selective ablation of one and only one population in two respects. First, following selective ablation the new P2 axons grow through ON fascicles that are very like normal having lost only about 0.1% of their fibers (less than the number that degenerate due to neuronal turnover – whether immature or not). The status of the ON itself seems to play some role during reinnervation judging by the loss of regional targeting during recovery from nerve transection. Second, the capacity to return to a specific region within the glomerular layer (true of the reinnervating axons with either selective or global destruction of the neurons) may reflect the fasciculation of like axons – not the P2 axons in this case, but all of the other types of axons that are targeting the area. In this interpretation, newly born, non-P2 neurons that target adjacent glomeruli may track or fasciculate along preexisting like axons to their proper target, that is, being actively directed away from the unoccupied P2 glomerulus. In contrast, the P2 neurons are not directed away from the P2 glomerulus, and would, therefore, have an advantage over unlike fibers in targeting it during their regeneration. In the free-for-all that would occur in the glomerular layer when preexisting axons are eliminated and a coherent wave of nascent fibers reach the bulb, it is only too easy to imagine that P2 or other axons would innervate multiple glomeruli and become stably ensconced in them. Some experimental evidence can be adduced for the importance of the preexisting fibers and the specificity of reinnervation. Neurons innervating atypical, necklace glomeruli at the posterior margin of the bulb are relatively less severely affected by MeBr lesion than the vast majority innervating the typical glomeruli, as a consequence of their concentration at the cribriform plate in areas relatively lacking cytochrome P450-expressing supporting cells. Thus, one can adjust the lesion conditions to spare about 50% of the preexisting neurons; in this case, the regenerated axons that target the necklace glomeruli end up reinnervating their original ones (which can be identified on the basis of position at the margin of the glomerular layer) (Ring, G. *et al.*, 1997). In contrast, lesions that destroy upward of 80% of the preexisting necklace neurons lead to mistargeting of necklace neurons into nonnecklace glomeruli.

4.34.6.3 Disorganization of the Projection Following Olfactory Nerve Transection

Although the projection of epithelium onto bulb is restored at the level of rhinotopy and receptotopy following MeBr lesion or other injuries to the periphery, ON transection results in significant changes to the ON projection patterns (Figure 3(c)). Following a complete transection of the ON, reinnervation of the bulb does not restore the normal topographical mapping of projections onto the OB (Christensen, M. D. *et al.*, 2001). The physical disruption of these nerves fibers and their perineural sheaths presents a challenge to regenerating nerve fibers as they grow back and reestablish connections in the bulb. The absence of guidance molecules present during early development as well as other factors may leave the regenerating axons with little or no cues to find their normal targets. ON transection experiments with P2-ITL mice show that regenerating axons often project widely across the OB during recovery, losing receptotopic specificity as shown by their innervation of multiple glomerular patches and losing rhinotopic specificity to a minor degree (Figure 3(c)) (Costanzo, R. M., 2000; 2005). Some of the regenerated axons projected diffusely while others innervated only a single locus in the bulb. In addition, while P2 nerve fibers continue to converge onto individual glomeruli, these glomeruli often received a mixed innervation that includes additional OR types. These results demonstrate that normal mapping of OR information onto the bulb is more substantially disrupted following recovery from nerve transection than after peripheral lesion. The remapping of odorant projections in the OB elicited by nerve transection potentially explains why animals must relearn how to perform odor discrimination tasks after recovery. Nonetheless, the rewired OB apparently provides sufficient spatial resolution of OR mapping to restore odor discrimination function.

4.34.6.4 Functional Recovery Following Epithelial Lesion or Nerve Transection

Despite the degradation in mapping of the OE onto the bulb after recovery from either peripheral injury or nerve lesion, there is a surprising degree of recovery in sensory function following the reconstitution of the epithelium and reinnervation of the bulb. In

the case of MeBr lesion, rats trained on a five-odorant identification task – a task on which they normally perform at 90% correct or better – show a rapid return to criterion performance when retesting begins at 2 months postlesion when the regenerated projection has stabilized (Youngentob, S. L. and Schwob, J. E., 1997). However, multidimensional scaling analysis of the patterns in the stimulus–response matrix across the animals indicates that the lesioned-recovered animals do perceive and process the test odorants differently than unlesioned animals tested after equivalent rest periods. In other words, the lesioned-recovered animals make different kinds of mistakes, that is, confusions, when performing the task.

Restoration of odor-mediated behavior following recovery from ON transection has been reported in a variety of species including the pigeon (Oley, N. *et al.*, 1975; Walker, J. C. *et al.*, 1981), goldfish (von Rekowski, C. and Zippel, H. P., 1993), mouse (Harding, J. W. and Wright, J. W., 1979), and hamster (Yee, K. K. and Costanzo, R. M., 1995). There is a direct correlation between the time course of OB reinnervation and recovery of odor detection and discrimination function. These studies raise an important question; does the perception of an odor change after recovery from nerve transection, when normal receptotopic specificity is lost? To address this question Yee K. K. and Costanzo R. M. (1998) studied performance on an odor discrimination tasks before and 40 days after ON transection in hamster. Animals were trained to discriminate between two unfamiliar odors, strawberry, and cinnamon, before surgery and then retested after 40 days of recovery. At this time point, the OB is reinnervated by a large number of newly regenerated ON fibers. Animals receiving a sham surgical procedure that leaves the ONs intact were able to perform the odor discrimination task 40 days after sham surgery, without food reinforcement. Those animals that received the nerve transection procedure performed at chance levels. However, if food reinforcement was given when the correct odorant was selected, recovery animals were able to relearn the odor discrimination task within a few days. When animals were tested on day 40 with completely new odors, baby powder, and coffee, both the sham and the reinnervated animals were able to learn the odor discrimination task within a few days. These results suggest that although there are likely to be alterations in the way nerve fibers reconnect to the OB following nerve transaction, after recovery these animals are capable of making odor discriminations but they must relearn the task. It is likely that the original perception of the odors as cinnamon and strawberry changed and that the animals must learn how to reinterpret these odors using the new mapping of ORs onto the bulb. Remarkably, the olfactory system has the capacity to restore its connections to the OB after injury, and even when significant changes occur to the OR mapping the animal can learn to use the new maps and recover olfactory function.

4.34.6.5 Summary

Aberrant connections are formed in the peripheral olfactory system following recovery from peripheral lesion or nerve transection. Rhinotopy and receptotopy – but not glomerultopy – are restored following epithelial lesion. In contrast, rhinotopy is somewhat compromised while receptotopy and glomerulotopy are severely disrupted following nerve transection. Nonetheless, neither form of lesion precludes sensory function following reconstitution of the epithelium and reinnervation of the bulb. However, the errors – which are of greater magnitude following nerve lesion – do change the encoding of odorants by the OB. Despite the reinnervation of the bulb, for these lesioned animals, as for humans presenting with olfactory dysfunction, a rose may no longer smell the same as a rose.

4.34.7 Conclusions and Unanswered Questions

The foregoing provides a summary of what we know of the recovery of the peripheral olfactory apparatus – the epithelium and its projection onto the bulb – following either reversible destruction of the epithelium or transection of the ON. From the phenomenological perspective, we now know the events that occur during epithelial reconstitution in substantial detail and those underlying reinnervation of the bulb somewhat less. However, our knowledge of cellular and molecular mechanism is still very far from complete. An integrated picture of the signals and transduction cascades that combine to regulate the choice point faced by the multipotent stem/progenitors is lacking and will remain obscure until certain conditions are met. Among them we need reagents and protocols that can be used to identify, isolate and characterize olfactory stem cells, and have them recapitulate the differentiation *in vitro* that they accomplish so effortlessly *in vivo*.

Once the stem cells are in hand, subsidiary questions of their therapeutic usefulness in the OE; for example, in replacing stem cells whose destruction or exhaustion underlies olfactory dysfunction, or in other settings, including their differentiation into OECs and implantation into injured spinal cord (Li, Y. *et al*., 1997), can be more profitably addressed. Likewise, we have little in-depth understanding of the mechanisms for maintaining the precision of axon targeting in the adult, which goes somewhat awry following epithelial lesion and is substantially disordered by injury to theON. If the sparing of preexisting fibers does promote accurate reinnervation, how are like-axons recognized and how do they form a substrate for growth? The recovery of olfactory function despite the scrambling of connections raises the specter of reorganization in central olfactory processing and leads to questions of whether sensory activity during the reinnervation process might impact that recovery. As our understanding of basic mechanism deepens it is reasonable to expect that useful therapies will begin to emerge.

4.34.8 Note Added in Proof

Subsequent to the preparation of this chapter a paper was published describing the contributions of HBCs to the repair of the OE following injury by MeBr or another direct acting toxin (Leung, C. T. *et al*., 2007). Their data report the use of a genetic lineage tracing technique in which cells that derive from HBCs are marked by the expression of LacZ due to the activation of Cre recombinase selectively in cells that make cytokeratin 5. In the epithelium of normal or bulbectomized mice, HBCs give rise only to HBCs throughout the life of the animal. However, after direct epithelial injury HBCs contribute to the roughly the same cell types as GBCs after transplantation, namely HBCs and GBCs themselves, neurons, sustentacular cells, and duct/gland cells; GBCs can give rise to respiratory epithelial cells, but HBCs have not yet been shown to give rise to them. Thus, it would appear that the HBCs, despite their relatively late emergence during the perinatal period in the development of the OE, serve as an additional reserve population with extensive multipotency *in vivo* and *in vitro* that is called upon when GBCs have been destroyed (a characteristic of the MeBr-lesioned mouse to a much greater extent than in lesioned rats). The persistence of two cell populations with the multipotency that is characteristic of tissue stem cells is reminiscent of other neurogenic populations, including that of the subventricular zone in the adult forebrain in which both type B and type C cells have the characteristics of neural stem cells. Furthermore, the situation in the olfactory epithelium may be a reflection of a more primitive character than that of the differentiated CNS. The GBCs share characteristics of the cells that compose the olfactory placode and the early stages of its invagination, including the expression of Pax6, Sox2, and, somewhat later, Mash1, before the HBCs emerge around the time of birth. The sequence may be conceptualized as if the primitive neuroepithelial cells of the neural plate and early tube are retained even after radial glia and subsequent glial forms of the subventricular zone emerge to serve as neurocompetent stem cells.

Glossary

adult neurogenesis The entire set of events leading to the production of new neurons in the adult brain, from precursor cell division to functionally integrated survival.

commitment Engaging in a program leading to differentiation. For a stem cell, this means exit from self-renewal.

green fluorescent protein (GFP) An autofluorescent protein that was originally isolated from the jellyfish *Aequorea victoria*. It can be genetically conjugated with proteins to make them fluorescent. The most widely used mutant, enhanced GFP (eGFP), has an emission maximum at 510 nm.

lentivirus vector A retrovirus vector derived from human immunodeficiency virus (HIV), which infects both dividing and nondividing cells.

multipotent Can form multiple lineages that constitute an entire tissue or tissues. Example: hematopoietic stem cells.

neurogenic niche Cellular microenvironment providing support and stimuli necessary to sustain self-renewal.

oligopotent Able to form two or more lineages within a tissue. Example: a neural stem cell that can create a subset of neurons in the brain.

pluripotent Able to form all the body's cell lineages, including germ cells, and some or even all extraembryonic cell types. Example: embryonic stem cells.

potency The range of commitment options available to a cell.

precursor CNS stem cells and all progenitors are generally referred to as precursor cells.

progenitor A mitotic cell with a fast dividing cell cycle that retains the ability to proliferate and to give rise to terminally differentiated cells, but is not capable of indefinite self-renewal.

stem cell A cell that can continuously produce unaltered daughters and also has the ability to produce daughter cells that have different, more restricted properties.

stem cells plasticity Unproven notion that tissue stem cells may broaden potency in response to physiological demands or insults.

totipotent Sufficient to form entire organism. Totipotency is seen in zygote and plant meristem cells; not demonstrated for any vertebrate stem cell.

transit-amplifying cell Proliferative stem cell progeny fated for differentiation. Initially may not be committed and may retain self-renewal.

two-photon microscopy Microscopy in which fluorochromes are stimulated, not by a single high-energy photon, but quasi-simultaneously by two photons of low energy, greatly reducing both light scattering and photodynamic sample damage.

unipotent Forms a single lineage. Example: spermatogonial stem cells.

4.35.1 Introduction

Modern neurobiology has shown that complex biological systems, such as the vertebrate brain, are constructed from similar, repeated units. In the central nervous system (CNS), these units, or modules, are composed of networks with opposite effects – excitation and inhibition. Excitation was initially assumed to play the dominant role in information processing, whereas inhibition was thought to prevent excessive activity. Local inhibitory neurons appeared to be simple elements that regulated excitatory neuronal activity. Thus, as in the Chinese Yin and Yang philosophy, the activity of a large network of principal excitatory (glutamatergic) neurons was thought to be purposefully balanced by local circuit inhibitory neurons.

The γ-aminobutyric acid (GABA)-releasing neuron, also referred to as the local circuit inhibitory interneuron, is one of the most studied types of interneuron. Recent investigations have indicated that the initial concept of interneuron is an oversimplification, requiring readjustment to accommodate cell types and functions that would not strictly fit the definition cited above. For instance, combined anatomical, electrophysiological, and pharmacological approaches have recently provided new insight into the roles of interneurons at several levels. At the cellular level, these cells govern action potential generation, firing pattern, precise timing of the discharge of individual principal cells in relation to the emergent behavior of the entire cell assembly, membrane potential oscillations, and dendritic calcium spikes. At the network level, inhibitory interneurons are considered to play an important role in controlling synaptic strength and plasticity and the generation of large-scale synchronous oscillatory activity.

Interneurons have generated considerable research interest, but studies of their function are limited by their tremendous heterogeneity in morphology and connectivity, the principal neurons being much more uniform in their appearance. This limitation has tended to push attempts to characterize interneuron subtypes into the domain of neurochemical content, based on calcium-binding proteins or neuromodulators. However, neurochemically identical cells may have surprisingly different functional properties, further complicating classification. Furthermore, as inhibitory interneurons exert pleiotropic effects on brain microcircuits, any characterization based solely on function is almost certain to prove problematic. Thus, a classification of interneurons can only be considered valid if it takes into account morphological, biochemical, and physiological characteristics. This criterion is satisfied for the first central relay of sensory information about odor, the olfactory bulb. This chapter provides an overview of the constitution of the bulbar interneuron population, current knowledge concerning the functions of these cells, their replacement and the possible role of adult neurogenesis in perception and memory. Due to space constraints, this review focuses exclusively on the mammalian olfactory bulb.

4.35.2 The Mammalian Olfactory Bulb Network

The main projection neurons of the bulb, the mitral cells, are located in a single lamina, the mitral cell layer (Figure 1). The primary dendrite of the mitral cell, extending vertically from the soma, contacts a single glomerulus, at which massive interactions with periglomerular interneurons and olfactory nerve terminals occur. Periglomerular interneurons are heterogeneous, including both GABAergic and dopaminergic subtypes. In contrast, mitral cell secondary dendrites radiate horizontally, for up to 1 μm, almost entirely spanning the olfactory bulb (Mori, K. *et al.*, 1983). In the external plexiform layer, they interact with inhibitory axonless interneurons – the granule cells – which constitute the largest cellular population within the bulb. The projection neurons engage with this extensive local circuit through dendrodendritic synaptic contacts. This reciprocal circuit provides the basis for the reliable, spatially localized, recurrent inhibition of mitral cells (Rall, W. *et al.*, 1966). The synaptic depolarization of mitral cells, driven by persistent excitatory input from the sensory neurons, triggers glutamate release from the dendrites of these cells, resulting in the depolarization of interneuron dendrites and spines. This, in turn, elicits the direct release of GABA into the mitral cell. Thus, in the olfactory bulb, the quality of the odor stimulus is initially encoded by a specific combination of activated mitral cells, as a function of GABAergic inhibition. As a single granule cell is believed to contact a number of output neurons (Shepherd, G. M. *et al.*, 2004), the reciprocal inhibitory synaptic connection helps to synchronize mitral cell activity (Lagier, S. *et al.*, 2004).

Following activation of the glomeruli, the network of output neurons and local interneurons adds a second

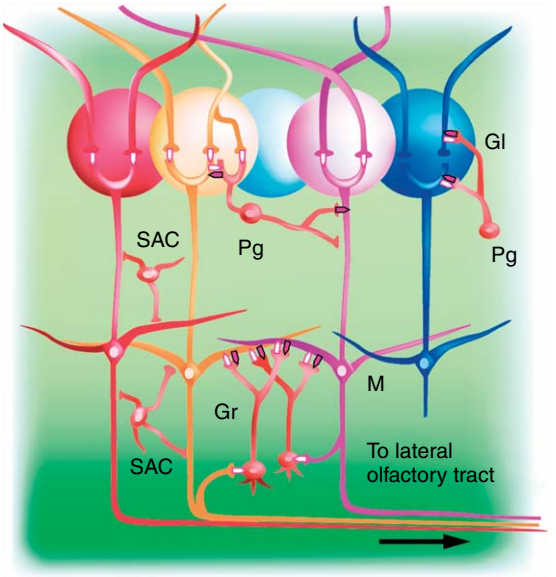

Figure 1 Wiring of the olfactory bulb. Each sensory neuron expresses only one of the 1000 odorant receptor genes and the axons from all cells expressing that particular receptor converge onto one or a few glomeruli (Gl) in the olfactory bulb. The nearly 2000 glomeruli in the rat olfactory bulb are spherical knots of neuropil, about 50–100 μm in diameter, which contain the incoming axons of sensory neurons and the apical dendrites of the projection neuron of the olfactory bulb, the mitral cell (M). Mitral axons leaving the olfactory bulb project widely to higher brain structures including the piriform cortex, hippocampus, and amygdala. Processing of the olfactory message into the bulb occurs through three populations of interneurons: periglomerular cells (Pg), granule cells (Gr), and short axon cells (SAC).

combinatorial layer to the representation of olfactory information. Contacts mediated by bulbar output neurons and local interneurons may contribute to the global reformatting of odor representations, in the form of a stimulus-dependent, temporal redistribution of activity across the olfactory bulb. In this context, lateral inhibition can be seen as a means of sharpening odor representation by a neuronal population (see below). Inhibitory circuits with different topologies are likely to form, depending on the sensory neuron afferents stimulated and the local interneuron connections activated following stimulation. Two combinatorial encoders therefore seem to be involved in information processing (Lledo, P.-M. *et al.*, 2005). The first is the olfactory receptor repertoire expressed by the ensemble of sensory neurons, which transduces receptor activation patterns into a glomerular odor image (Korsching, S., 2002). The secondary encoder is the intricate interneuron network, which extracts higher-order features from the odor images, converting them into timing relationships across the firing output neurons (Laurent, G., 2002). Three assumptions can be made, based on the combination of these two encoders of the olfactory bulb. First, the neural synchronization of glomerular outputs may enhance the representation of a complex olfactory stimulus by integrating the different signal streams activated by the odor into a unified olfactory image in the sensory cortex. Second, the activation of neuronal assemblies in the bulb modulates groups of neurons in the forebrain, bringing into play an olfactory signal-decoding mechanism. It has been suggested that the olfactory forebrain uses coincidence detector neurons to identify the various patterns of activity in the bulb (Mori, K. *et al.*, 1999). In this model, synchronized oscillations are seen as a means by which signals from different olfactory neurons are temporally connected for detection. Finally, the neurons in the olfactory bulb that relay activity to the rest of the brain interact extensively with each other, both directly and through a network of coupled interneurons. The relay neurons can engage in highly synchronous oscillatory activity, thereby forming assemblies that conveying information about a particular odor blend. As described below, the continuous turnover of interneurons plays an important role in adjusting the spatiotemporal processes of the olfactory bulb to the level of complexity and novelty of odors encountered by the animal.

4.35.3 Building Neuronal Networks during Adulthood

Postdevelopmental neurogenesis is conserved across evolutionary boundaries, from crustaceans to higher vertebrates, such as birds, rodents, and primates, including humans. The extent of postnatal neurogenesis decreases with increasing brain complexity, with adult neurogenesis in lower vertebrates, such as lizards, providing a massive additional supply of neurons capable of regenerating entire areas of the brain, whereas mammalian neurogenesis is restricted to only a few regions of the brain and to the replacement of newborn neurons. The degree of postdevelopmental neurogenesis in a given species may depend on a trade-off between the benefits accruing from the creation of new neurons and the problems generated by these neurons in terms of their integration into the network circuitry. In more complex brains such as those of mammals, the problems of newborn neuron integration seem to outweigh the potential benefits and adult

neurogenesis in normal conditions is probably confined to just two regions: the subgranular zone of the hippocampal dentate gyrus and the subventricular zone (SVZ), which contributes interneurons to the olfactory bulb (Alvarez-Buylla, A. and Garcia-Verdugo, J. M., 2002). There is some evidence to suggest that constitutive neurogenesis occurs in other regions of the adult brain, but this remains to be demonstrated (Rakic, P., 2002).

4.35.3.1 Producing New Neurons

Astrocytes in the adult SVZ, which lines the border between the striatum and the lateral ventricle to form a neurogenic niche, act as slow-dividing adult neural stem cells with high potency, generating transit-amplifying cells before transforming into neuroblast precursors (Doetsch, F., 2003) (Figure 2). These neuroblasts proceed toward the olfactory bulb along an intricate path of migration known as the rostral migratory stream (RMS). More than 30 000 neuroblasts leave the rodent SVZ and enter the RMS each day (Alvarez-Buylla, A. and Lim, D. A., 2004). In the RMS, they are not guided by radial glia, but instead migrate tangentially in chains through tubular structures formed by specialized astrocytes. These newborn cells then detach from the chains and migrate radially into the olfactory bulb, where they mature into olfactory inhibitory interneurons of two main types – granule cells and periglomerular cells – and integrate into networks. Both these cell types make only local contacts, directly or indirectly modulating the processing of sensory information by the mitral cells.

4.35.3.2 Maturation and Functional Integration

The use of replication-incompetent lentiviruses to transduce stem cells in the SVZ and label them with enhanced green fluorescent protein (eGFP) has made it possible to characterize the commitment of adult stem cells. The presence of GFP has made possible both morphological and electrophysiological characterization of the newly formed olfactory bulb neurons during their migration and differentiation (Belluzzi, O. *et al.*, 2003; Carleton, A. *et al.*, 2003). The morphology of newly generated cells becomes more complex in the first few weeks after their generation. Granule cells form more elaborate dendrites extending into the external plexiform layer of the bulb, and become fully mature morphologically within about 2 weeks. In contrast, periglomerular cells may take about 4 weeks to develop their full dendritic and axonal morphology (Belluzzi, O. *et al.*, 2003); a period of time similar to that required for the maturation of hippocampal cells generated during adulthood (Figure 3). During this maturation, immature bulbar interneurons express transient marker proteins, including TUJ1 and TUC4 (Lledo, P.-M. *et al.*, 2006). Functionally, as in the adult hippocampus, the first synapses made with new cells are GABAergic, and these contacts are followed by glutamatergic inputs several days later. The developmental sequence of voltage-dependent currents and synaptic connections differentiates between newly formed periglomerular and granule cells (and between bulbar and hippocampal granule cells). In periglomerular cells, maturation of the voltage-dependent sodium current, and consequently the capacity of the newly generated cells to fire action

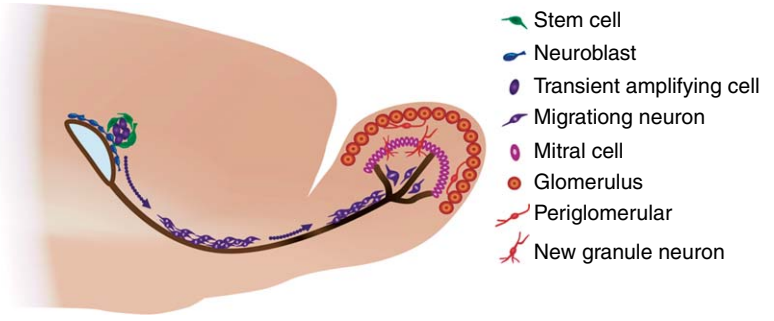

Figure 2 The subventricular zone (SVZ)–olfactory bulb pathway constitutes one of the two neurogenic niches in the adult forebrain. Mauve arrows indicate the tangential migration of neuroblasts from the lateral ventricle (filled in blue) toward the olfactory bulb. Neurogenesis refers to the replacement of bulbar local interneurons in the olfactory bulb.

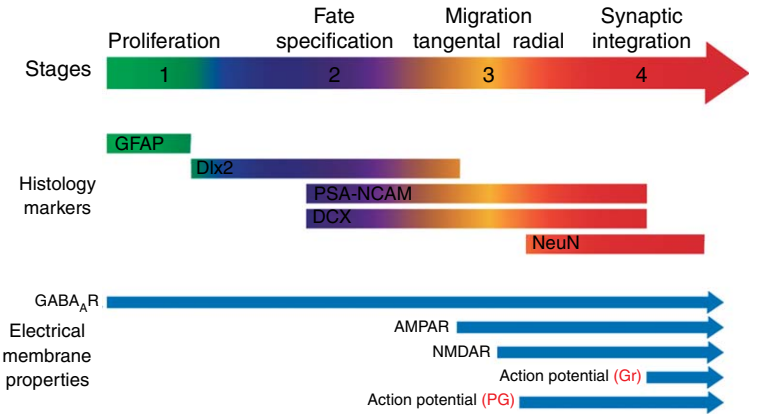

Figure 3 Postmitotic maturation of newborn neurons in the adult forebrain. The schema shows the functional stages through which adult-born neuron progress before becoming fully mature. This simplified state of affairs comes with a number of caveats, since the maturation of individual adult-born neurons has yet to be followed, maturation stages are likely to reflect a continuum rather than discrete steps, and maturation time points are likely to vary considerably from cell to cell. For this last reason, ages here represent the earliest age at which particular properties have been observed in a given cell type. Note also that maturation certainly does not stop at stage 4: arbor complexity and spine density can increase up to 4 months after the birth of a newborn neuron. It is noteworthy that receptor expression precedes synaptic activation, and γ-aminobutyric acid (GABA)-mediated input precedes glutamatergic input. Olfactory bulb granule cells show atypical maturation in that they only fire sodium-based action potentials after they have begun to receive synaptic input.

potentials, seems to precede the appearance of synaptic contacts, whereas the opposite pattern is observed in granule cells (Belluzzi, O. *et al.*, 2003; Carleton, A. *et al.*, 2003). The later maturation of granule cell excitability may prevent the preexisting circuitry in the adult from being disrupted during the insertion of newly formed cells. Alternatively, as even mature granule cells lack an axon, it may result purely from morphological differences between granule and periglomerular neurons. Further studies are required to determine whether newly generated neurons form functional synapses with their downstream target neurons and release appropriate neurotransmitters, which would unequivocally demonstrate their integration into adult networks.

Below, I summarize the contributions of early work in the field to the current framework for understanding the role of newborn interneurons in the adult olfactory bulb network. I will also review the more recent findings that have dramatically reshaped our view of the integration of newly formed neurons into adult networks. At first glance, this neurogenesis may be seen as a putative response to the death and turnover of the primary olfactory receptor neurons that occurs throughout the life of the animal. However, as we will see below, adult neurogenesis also endows the bulb with unique properties.

4.35.4 Functions of Newly Formed Interneurons in the Olfactory Bulb

Ongoing neurogenesis and migration in adults have been extensively documented, but their functional consequences remain unclear. As the largest neuronal population in the olfactory bulb consists of granule cells, which outnumber the projection neurons by at least 100:1 (Shepherd, G. M. *et al.*, 2004), and one granule cell contacts several mitral cells, with each mitral cell, in turn, contacting a large number of pyramidal cells from the pyriform cortex, the integration of transient newly formed neurons into an upstream position in the olfactory bulb is ideal for amplifying the effects of neurogenesis throughout the olfactory pathway. If the continuous generation of interneurons throughout the animal's life is necessary for olfaction, then changes in migration processes – resulting in changes in the recruitment of new interneurons – should affect olfactory processing. Studies of transgenic mice with low levels of adult neurogenesis have been carried out to test this hypothesis. For example, NCAM-mutant mice have been studied as these mice display lower than normal levels of neuroblast migration. The quantification of bulbar neurogenesis revealed 40% fewer newly formed interneurons in adult knockout mice than in the wild type.

This impairment of neurogenesis was accompanied by changes in odor discrimination (Gheusi, G. *et al.*, 2000), revealing a specific role for newly formed interneurons in the downstream coding of olfactory information. This observation was supported by observations in another transgenic line with impaired $GABA_A$ receptor-mediated synaptic inhibition (Nusser, Z. *et al.*, 2001) and by theoretical analyses (Cecchi, G. A. *et al.*, 2001). Based on these data, it appears that a critical level of inhibition, mediated by the activation of $GABA_A$ receptors located on the secondary dendrites of bulbar projection neurons, is required for olfactory processing. In addition, as the olfactory bulb is also involved in consolidating processes associated with long-term odor memory, changes in the number of GABAergic interneurons may regulate both olfactory perception and memory.

This issue has been investigated, by studies aiming to determine whether a change in the number of newly formed bulbar interneurons alters olfactory memory. In these experiments, animals were reared in a complex olfactory environment. Exposure to enriched sensory surroundings has many positive effects on brain structure and function, increasing the number of dendritic branches and spines, enlarging synapses, increasing the number of glial cells and improving performance in tests of spatial memory (Rosenzweig, M. R. and Bennett, E. L., 1996). Mice reared in enriched olfactory environments produce twice as many new interneurons as other mice. This increase is specific to the olfactory bulb, with no changes observed in the other neurogenic zone, the dentate gyrus of the adult hippocampus. Animals with higher levels of neurogenesis retain learned olfactory information for longer periods of time than controls (Rochefort, C. *et al.*, 2002). In particular, animals reared in enriched olfactory environments recognize familiar odors in more readily and in a more sustained manner than animals reared in standard conditions. Although the potential consequences of an enriched environment for synaptic efficacy and/or mitral cell activity were not specifically explored, these results are consistent with the existence of a correlation between the size of the newly formed interneuron population and odor memory.

4.35.5 Properties Conferred by Neurons Generated in Adulthood

Although recent estimates suggest that many more neurons are produced during adulthood than was initially thought, the estimated rate of neuron production in adulthood remains lower than that during development. Consequently, if the neurons generated during adulthood have similar functional properties to those generated in early life, then adult neurogenesis probably has an insignificant impact. In contrast, if adult-generated neurons have unique properties, giving them a greater impact than more mature neurons, then their continual integration into the functional circuitry would be expected to have major effects. Recent observations of both the hippocampus and the olfactory bulb are consistent with this second hypothesis. Indeed, newly formed neurons seem to display robust plasticity that cannot be inhibited by GABA, which is not the case for mature neurons. As new neurons are structurally plastic (Figure 4), they may well be very sensitive to changes in the animal's environment and life experiences. This suggests that adult neurogenesis is functionally important, as it results in a continual influx of neurons that are, at least temporarily, immature, with unique physiological properties.

As described above, bulbar interneurons play an essential role in shaping the olfactory information that reaches the olfactory cortex. As the cells generated in the adult SVZ differentiate exclusively into bulbar interneurons, they probably contribute to essential aspects of olfactory processing. Experimental studies and modeling have provided evidence that newly formed granule cells play a role in olfactory discrimination, but the more general functions of these cells remain to be characterized. Adult neurogenesis is unlikely to be of immediate functional

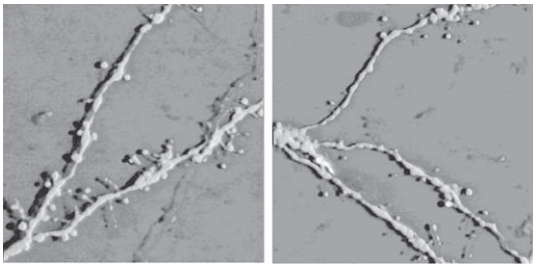

Figure 4 The adult neurogenesis brings plastic elements to preexisting neuronal networks. Images of green fluorescent protein (GFP)-labeled newborn interneurons taken with a two-photon microscope. The newborn interneurons developed in active (left panel) or inoperative (right panel) olfactory bulb networks. Note reduced spine density for newborn interneurons maturing in the quiescent olfactory bulb.

benefit, because it takes several days to generate a new, functionally integrated interneuron (Figure 3). Cells generated during adulthood develop neurites within a few weeks. It is clear that the new connections cannot constitute a response to the particular functional event triggering neurogenesis, because these connections may well not form until after the trigger event has ended. Olfactory bulb neurogenesis should therefore be considered a long-term, as opposed to a short-term adjustment of the bulbar circuitry to a higher level of experience governed by olfaction.

4.35.6 Adult Neurogenesis: A Neural Basis for Experience-Induced Plasticity

It seems reasonable to assume that the mind and brain benefit from active living; this hypothesis is supported by several observations, including the results of epidemiological studies. It has also been clearly established that both physical and intellectual activities have a positive influence on the incidence of neurodegenerative disorders and cognitive decline. The continuous neurogenesis observed in the olfactory region of adult animals provides us with a unique model for studying the effects of sensory-driven activity and its benefits. In the olfactory bulb, the role of environment-induced activity can be explored not only during the neonatal period, when the developing structures are refined and stabilized, but also in adulthood, when more delicate regulation occurs. Several studies have demonstrated that changes in the level of sensory activity do not affect the proliferation and tangential migration of neuroblasts. Instead, they seem to regulate the number of newly generated neurons reaching the olfactory bulb and the level of cell death. Thus, sensory-driven activity may play an important role in several steps of adult neurogenesis (Figure 5). This, in turn, would greatly modify the number of new interneurons, thereby altering the inhibitory–excitatory balance in the bulbar neuronal networks. There is clear evidence that adult neurogenesis can be regulated, but most of the data on adult mammalian neurogenesis have been obtained from laboratory animals, kept under artificial conditions very different from their natural habitat. Even the odor-enriched environments used in experiments are arguably much poorer in terms of sensory stimulation than conditions in the wild.

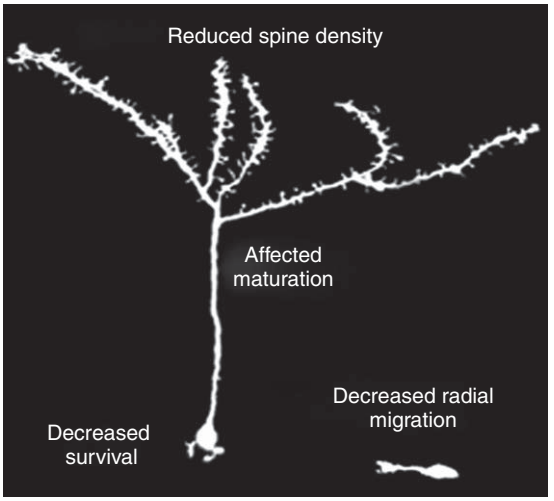

Figure 5 Role of sensory activity in shaping the adult neurogenesis. Using sensory deprivation paradigm, it has been demonstrated that odor-induced activity is required for normal radial migration of neuroblasts, their survival and maturation and the maintenance of spine density.

4.35.7 Ethological Relevance of Adult Neurogenesis

Although it is clear that the adult olfactory bulb integrates neurons throughout life, the reason for this remains unclear. What are the new neurons used for and how can an existing functional neural network integrate and even actively recruit new neurons? Current theories concerning cognition are based on the assumption that the adult brain is a stable network in terms of the number of neurons. According to this scheme, structural neural plasticity occurs only at the level of synapses, dendrites, and neurites. The demonstration of adult bulbar neurogenesis – the generation of new interneurons from resident neuronal stem cells and their integration into the bulbar circuit – has called this assumption into question. In light of results on the activity-dependent regulation of adult bulbar neurogenesis, some conclusions concerning why and how new neurons contribute to bulbar function can be made. I suggest that neurogenesis does not simply add neurons to enhance memory, but that it also strategically inserts new cells with unique properties (Figure 3). The multiple stages in the maturation of new neurons might provide a more extended substrate for plasticity. The newly formed neurons may provide the olfactory bulb with a large repository of plastic cells, enabling it to respond more effectively to

changes in the environment and to life experiences (Figure 5). For instance, new neurons may respond preferentially to hormones, learning, and other forms of experience-induced activity. These aspects have been well documented in various biologically relevant models described briefly below.

Female mice form a memory of the pheromones of the male they mate with, a phenomenon known as the Bruce effect. This memory leads to disruption of the pregnancy when the female is exposed to the pheromones of other males (Bruce, H. M., 1959). It is formed during mating and requires a period of about 3–4 h of exposure to the male's pheromones. Brennan P. A. *et al.* (1995) used a microdialysis approach to explore changes in a range of neurotransmitters that occur when female mice form a memory of their stud male. The main change in the accessory olfactory bulb is a decrease in glutamate/GABA ratio following memory formation in response to the mating male's pheromones. The increase in GABA release reflects a higher inhibitory tone at the reciprocal synapses. Brennan P. A. *et al.* (1995) interpreted this mechanism as a way of reducing excitation from mitral cells, which mediate the input from the mating male's pheromones, prevent the blockage of pregnancy. In contrast, exposure to a different male would activate a different subpopulation of mitral cells, not previously subjected to an increase in inhibitory control, thereby eliciting central pregnancy-blocking mechanisms. These processes are not restricted to the formation of a memory of the mating male's pheromones. Similar events have been observed in the olfactory bulb of ewes during the development of a specific ability to recognize their own lambs, enabling them to reject other lambs that attempt to suckle. After parturition, an increase in glutamate and GABA release occurs in the ewe's olfactory bulb in response to odors from her own lamb, but not to odors from other lambs (Kendrick, K. M. *et al.*, 1992). Once the ewe has established a selective bond with its lamb, the ratio of glutamate to GABA decreases in response to the lamb's odor, suggesting, once again, the existence of changes in the gain of reciprocal synapses between mitral and granule cells.

These examples illustrate changes in the excitatory–inhibitory balance in the olfactory bulb occurring during the establishment of specific social preferences. Similar changes have recently been shown to occur in circumstances involving olfactory learning in a broader context. For instance, the use of a conditioning procedure in which adult mice were trained, using odor, to dig through wood shavings to obtain a buried piece of sugar, has produced interesting findings. Following conditioning, the presentation of the odor previously associated with the reward induces an increase in both glutamate and GABA levels in the olfactory bulb and a decrease in the balance between excitatory and inhibitory transmitters. In contrast, no change is observed if animals are exposed to a nonconditioning odor, indicating that the increase in inhibition occurs only for relevant odors. These findings highlight the significance of the changes in the excitatory–inhibitory ratio that occur in the olfactory bulb following learning. The neurochemistry of inhibition enhancement is reminiscent of the upregulation of the permanent supply of bulbar interneurons correlated with a stronger memory in odor-enriched mice. Together, these findings indicate that adult bulbar neurogenesis may be involved in many natural types of behavior yet to be explored.

4.35.8 Concluding Remarks

We still do not know why there are new neurons in the adult brain, but research into the regulation of adult neurogenesis, and an increasing number of studies investigating the function of the new cells, have led to two conclusions. First, bulbar neurogenesis is affected by relevant behavior, including behavior specifically related to bulbar function, in particular. Second, changes in the rate or extent of neurogenesis have an effect on subsequent behavior. Thus, behavior may change the structure of the olfactory bulb, and changes in structure can subsequently modify, or at least affect, subsequent behavior. The correlation between activity and adult neurogenesis suggests that new neurons are involved general aspects of bulbar function, probably sustaining the ability of the adult network to adapt information processing to relevant ethological needs.

The sense of smell has played an essential role in mammalian evolution. Odor representation is dynamic and highly complex, and may require unique plasticity mechanisms. Neurogenesis, migration, and the replacement of new neurons in the olfactory bulb are probably involved in this adaptive mechanism. As it takes time for new neurons to mature and become integrated into synapses, adult neurogenesis probably contributes to slow, long-term adjustments of the bulbar circuitry, rather than to fast and acute plastic changes. However, new neurons

may also be involved in faster mechanisms. Several new bulbar interneurons die within a month of maturation. Recent results show that newly formed granule cells maintain synaptic contacts during this period of rapid cell death. The selective elimination of neurons may make it possible to modify the circuitry more rapidly. The ability to mold the integration of new neurons and to eliminate older cells continually, without depleting the neuronal population, may provide neuronal networks with adaptive potential unequalled by synaptic plasticity alone.

In this brief review, I have tackled two of the main problems relating to the existence of newborn neurons in the adult olfactory bulb. Both are fundamental issues. First, I have discussed the role of adult neurogenesis in the context of bulbar function. Assuming that the bulb processes odor information before relaying it to the olfactory cortex, I hypothesize that adult neurogenesis allows the olfactory bulb to adjust the degree of processing appropriately. Second, the existence of a pool of juvenile neurons, enabling the system to adapt to future similar situations, raises the possibility that adult neurogenesis acts *post hoc* to provide a structural basis for brain plasticity. Research on adult neurogenesis in the olfactory bulb is thus not only interesting in itself, but also provides new avenues of exploration to increase our understanding of adult brain plasticity.

Glossary

cilia Nonmotile extensions of the olfactory sensory neurons within the lumen of the nasal cavity. The cilia are suspended in a layer of mucous, express odor receptors on their surface, and increase significantly the surface area of the olfactory sensory neurons.

dendrodendritic synapse Synapses occurring between two dendrites or between a dendrite and a dendritic spine. In the olfactory bulb dendrodendritic synapses form between mitral/tufted cells and granule cells in the external plexiform layer and between mitral/tufted cells and peri/juxtaglomerular cells in the glomerular layer.

gap junctions Intercellular channels that allow the diffusion of ions and metabolites and constitute the structural basis of electrical synapses. They may be

homotypic, composed of identical hemichannels (or connexons) provided by each of the connected cells, or heterotypic, composed of different connexons. In vertebrates, each connexon is normally a hexamer of connexins.

glomerulus Spherical area of neuropil where olfactory sensory neuron axons terminate and make synaptic contact with mitral, tufted, and periglomerular cells. Glomeruli are molecularly homogeneous in that all of the sensory axons terminating in one glomerulus arise from sensory neurons expressing the same odor receptor.

granule cell A major interneuron in the olfactory bulb. Granule cells are anaxonic, they lack axons, and both input and output synapses occur through specialized dendritic spines found on their apical dendrites within the external plexiform layer. Granule cells establish these dendrodendritic synapses with the secondary dendrites of mitral and tufted cells. Input synapses, from centrifugal fibers and axon collaterals of mitral and tufted cells, also occur at the cell bodies and basal dendrites in the granule cell layer. New granule cells continue to be generated in the adult and migrate into the olfactory bulb via the rostral migratory stream.

lateral olfactory tract A myelinated tract of axons from mitral and tufted cells extending from the olfactory bulb to the cortex. As axons exit the lateral olfactory tract they terminate in layer Ia of cortex, where they synapse on the apical dendrites of cortical pyramidal neurons.

mitral cell Major projection neuron from olfactory bulb to cortex. The cell bodies comprise a monolayer in the adult olfactory bulb. The apical dendrite arborizes in a single glomerulus while the lateral dendrites extend out in the external plexiform layer perpendicular to the radial axis of the olfactory bulb. The mitral cell axons distribute broadly in piriform cortex.

olfactory ensheathing cells Glia that encompass fascicles of olfactory sensory neuron axons in the olfactory nerve and in the olfactory nerve layer of the olfactory bulb. The ensheathing cells are important in the ongoing growth of new axons from the epithelium to the olfactory bulb. Due to their ability to support axon outgrowth in the olfactory system, the ensheathing cells have also found application in spinal cord injury where transplants of the ensheathing cells can improve axon regeneration.

olfactory nerve A collection of olfactory sensory neuron axon fascicles, surrounded by the processes of olfactory ensheathing cells, that extends from the olfactory epithelium to the olfactory bulb. As the nerve merges with the olfactory bulb, it becomes the olfactory nerve layer.

olfactory sensory neuron A specialized receptor found in the olfactory epithelium. The apical dendrite extends in the lumen of the nasal cavity where multiple cilia extend. The olfactory sensory neurons each express only 1 of 1000 different odor receptors in rodents. The olfactory sensory neurons are derived from a population of basal cells that appear to provide for ongoing replacement of the sensory neurons throughout life.

peri/juxtaglomerular cells These surround the glomeruli of the olfactory bulb and extend dendritic processes into the glomeruli where some receive input from the olfactory sensory neuron axons and most participate in dendrodendritic synapses with the apical dendrites of mitral and tufted cells. Axons from the peri/juxtaglomerular cells can extend considerable distances in the glomerular layer to mediate interactions with distant glomeruli. Peri/juxtaglomerular cells can be further divided into multiple subpopulations based on their molecular phenotype including the expression of neurotransmitters and calcium-binding proteins. Like granule cells, peri/juxtaglomerular cells continue to be generated in the adult.

rostral migratory stream A well-defined glial lined tract via which neuroblasts from the subventricular zone migrate into the olfactory bulb.

sustentacular cells Nonsensory supporting cells that surround the olfactory sensory neurons in the olfactory epithelium. The sustentacular cells may contribute to the removal of odorants or other molecules from the nasal cavity.

tufted cell Includes three subpopulations of olfactory bulb neurons. Deep and middle tufted cells, named for the positions of the cell bodies in the external plexiform layer, are organized and project to higher regions in a manner similar to that of mitral cells. External tufted cells are proximal to the glomeruli and mediate intrabulbar connections.

4.36.1 Introduction

The olfactory bulb is the first relay in the processing of volatile odor information in the central nervous system. Odor processing begins in the olfactory epithelium (OE), where the sensory neurons are located, and then proceeds in a hierarchical manner into the olfactory bulb, followed by primary olfactory (piriform) cortex. Tertiary cortical projections are widespread throughout the neuroaxis. As has been noted previously, the fundamental principles of organization and information flow in the olfactory system are broadly conserved across species as well as phyla.

The volatile signals processed by the olfactory system are used widely in regulating feeding behavior and preferences, avoidance, territorial marking, recognition of self versus nonself, emotional states, among others. A comprehensive review of the behavioral significance of the olfactory system is beyond the scope of this chapter, as is a fully integrated description of hierarchical organization of the pathway. The focus here will be on the structural and synaptic organization of the olfactory bulb, with reference to the OE and primary olfactory cortex as needed to help interpret general architectural principles found in the olfactory bulb. Because the organization of olfactory systems, and the olfactory bulb in particular, is widely conserved, much of the information presented here will be based on studies carried out in rodents. As will be reviewed below, the olfactory bulb is laminated, like an onion, and includes a minimum of seven primary layers: (1) the olfactory nerve layer (ONL); (2) the glomerular layer; (3) the external plexiform layer (EPL); (4) the mitral cell layer; (5) the internal plexiform layer (IPL); (6) the granule cell layer; and (7) the subependymal layer or rostral migratory stream. Each of the layers is distinguished by its cellular composition and/or synaptic organization. We will begin with a brief review of the OE because it gives rise to the axons that will constitute the outermost layer of the olfactory bulb.

We apologize to those whose work has not received appropriate attention in this chapter due to space limitations. For further details on aspects of the organization of the olfactory bulb discussed here, readers are referred to several recent excellent and comprehensive reviews (Shepherd, G. M. *et al.*, 2004; Lledo, P. M. *et al.*, 2006; Wachowiak, M. and Shipley, M. T., 2006).

4.36.2 Nasal Cavity

4.36.2.1 Olfactory Epithelium

Odor processing begins in the OE where odorants, ligands, bind with subpopulations of olfactory sensory neurons (OSNs). The epithelium is pseudostratified and includes three primary populations of cells: the OSNs, sustentacular or supporting cells, and a basal cell population that generates new sensory neurons throughout life (Graziadei, P. P. C. and Monti-Graziadei, G. A., 1978; Newman, M. P. *et al.*, 2000). The sensory neurons are highly polarized, with an apical dendrite extending to the epithelial surface where it enlarges to include multiple cilia and a thin axon (~0.2 μm in diameter) extending from the basal pole (Cuschieri, A. and Bannister, L. H., 1975). Deep to the basal lamina, the axons coalesce into fascicles that ascend and become the olfactory nerve. As the axons exit the epithelium, they are accompanied by a specialized glia cell, the olfactory ensheathing cell/glia (OEC) (Doucette, J. R., 1984). While the axons remain unmyelinated, processes from the OECs do surround the fascicles of the olfactory nerve and interdigitate among the axons. Diverse lines of evidence suggest that the OECs play an important role in the ability of the olfactory nerve to sustain continued axon growth as new sensory neurons are generated (Kafitz, K. W. and Greer, C. A., 1999).

Since the identification in 1991 (Buck, L. and Axel, R., 1991) of the large family of genes (~1000 in rodents) coding for odor receptors (ORs), the tools of molecular biology have provided for unique insights into the organization of the OE and nerve. The OSNs are believed to express only one functional OR (Chess, A. *et al.*, 1994; Serizawa, S. *et al.*, 2003), and the application of embryonic stem cell engineering has allowed the introduction of markers, either LacZ or GFP, downstream from the promoters of specific ORs (Mombaerts, P. *et al.*, 1996). Thus, the full repertoire of sensory neurons expressing a specific OR can be visualized in their entirety, from their cell bodies in the OE to the terminal portions of their axons in the olfactory bulb. Although axons of the OSNs expressing the same OR coalesce onto one or two glomeruli in the olfactory bulb (typically one glomerulus on each side of the olfactory bulb), the cell bodies are stochastically distributed within a limited region/zone of the OE (Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993; Miyamichi, K. *et al.*, 2005) where they neighbor with OSNs expressing different ORs. Initially, it was thought that the OE was delimited into four distinct

zones, each of which contained a specific subset of ORs (Ressler, K. J. *et al.*, 1993; Vassar, R. *et al.*, 1993). The most recent evidence, however, is that while each OR has a very limited band of expression within the OE, these are contiguous and overlapping (Iwema, C. L. *et al.*, 2004; Miyamichi, K. *et al.*, 2005). The heterogeneous mixture of molecularly defined OSNs continues as their axons exit the OE; axon fascicles within the OE but deep to the basal lamina are initially composed of heterogeneous populations of axons and show no evidence of topographical sorting.

The olfactory nerve exits the OE as the fascicles begin to enter the cranial cavity via a series of small foramen in the cribiform plate of the ethmoid bone. As the nerve contacts the rostral and rostral–ventral quadrants of the olfactory bulb, a complex process of defasciculation begins and the outermost layer of the olfactory bulb, the ONL, is formed (Au, W. W. *et al.*, 2002) (Figure 1).

4.36.3 Olfactory Bulb – Laminar Organization

4.36.3.1 Olfactory Nerve Layer

The OECs that were associated with the OSN axons as they exited the OE continue to define the organization of fascicles in the ONL. The OECs in the outermost olfactory nerve layer (ONLo) express the low-affinity nerve growth factor receptor p75 (Au, W. W. *et al.*,

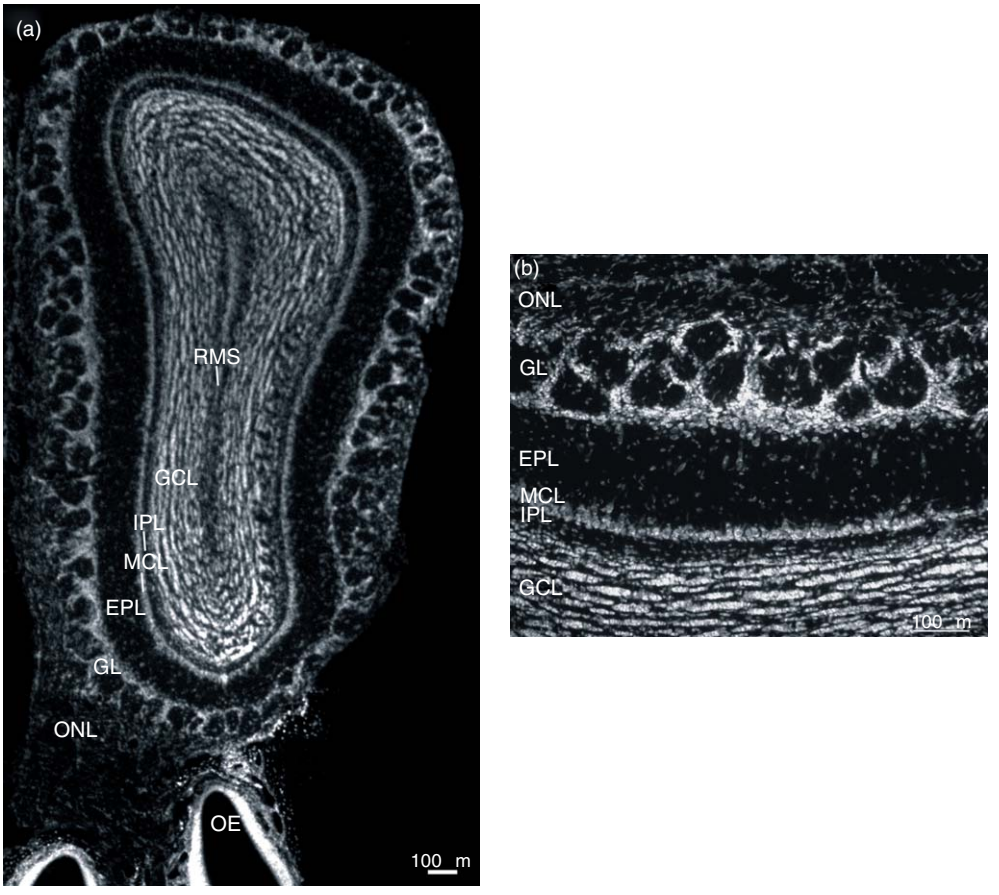

Figure 1 (a) Nissl-stained transverse section of the mouse olfactory bulb showing the laminar organization. The dorsal recess of the nasal cavity and olfactory epithelium are seen below. The spherical glomeruli delineated by periglomerular cells, the paucity of cells within the external plexiform layer, and the well-defined mitral cell layer and deeper granule cell layer are distinctive features of the olfactory bulb. Note that at this level, the laminae are continuous around the circumference of the olfactory bulb. (b) Higher magnification image of the Nissl-stained olfactory bulb. Note the differences in the sizes of the cells surrounding the glomeruli, periglomerular versus juxtaglomerular, and the large cell bodies in the mitral cell layer. The granule cells are distributed in clusters, islets, between which axons from both mitral/tufted cells and centrifugal axons travel. ONL, olfactory nerve layer; GL, glomerular layer; EPL, external plexiform layer; MCL, mitral cell layer; IPL, inner plexiform layer; GR, granule cell layer; RMS, rostral migratory stream; OE, olfactory epithelium. Calibration bars, 100 μm.

2002), while those in the inner nerve layer (ONLi) express the transcription factor TROY (Hisaoka, T. *et al.*, 2004). In parallel, the organization of fascicles differs in the ONLo and ONLi (Au, W. W. *et al.*, 2002). In the former, fascicles defined by the processes of the OECs are small, well defined, and tend to have axons with aligned trajectories. In the ONLi, the fascicles are larger and the trajectories of axons are often mixed. This has led to the suggestion that axons in the ONLo are *en route* while those in the ONLi are reorganizing into molecularly homogeneous fascicles that will coalesce into the same glomerulus. Throughout their length, the OSN axons remain fairly stable with a diameter of ~0.2 μm, but as they enter the ONLi and draw proximal to the glomerular layer, they increase somewhat in diameter to ~0.3 μm. Similar increases are seen elsewhere in the nervous system as axons begin to approach a target region of arborization and synapse formation. OSN axons do not branch within the ONL; arborization of the axons occurs after they enter a glomerulus (Klenoff, J. R. and Greer, C. A., 1998) (Figure 2).

4.36.3.2 Glomerular Layer

The glomeruli of the olfactory bulb, like glomeruli elsewhere in the nervous system, are compact areas of neuropil and contain the first synapses from the OSN axons. The glomeruli are encapsulated by glia cells, some of which extend processes into the neuropil (Kasowski, H. J. *et al.*, 1999; Wachowiak, M. and Shipley, M. T., 2006 for detailed review). In addition, glomeruli are delineated by a large population of peri- and juxtaglomerular cells.

The OSN axons penetrate a glomerulus at the top, predominately from the ONLi, although many examples are found of single axons or very small fascicles of two to five axons that enter from a variety of tangents (Treloar, H. B. *et al.*, 2002) including the EPL (see below). Within the glomerulus, each axon arborizes to generate 10–12 branches, each of which ends in a terminal bouton (Klenoff, J. R. and Greer, C. A., 1998). The OSN axons within the glomerulus also characteristically have varicosities along their length. Both the varicosities and terminal boutons establish synapses with the dendrites of the projection neurons, mitral and tufted cells, and interneurons, the peri/juxtaglomerular cells (Kasowski, H. J. *et al.*, 1999).

A hallmark of glomerular organization is the specificity with which a subset of axons coalesce within a specific glomerulus. As noted above, while all of the OSNs expressing a specific OR are broadly distributed across a restricted zone in the epithelium, after their axons reach the olfactory bulb, they defasciculate and reorganize into fascicles targeted for a specific region of the bulb (i.e., caudal–medial). The refinement of fascicles into more homogeneous collections of axons that express the same OR occurs when the axons are proximal to the glomerulus, predominately within the ONLi. While early in development there is evidence

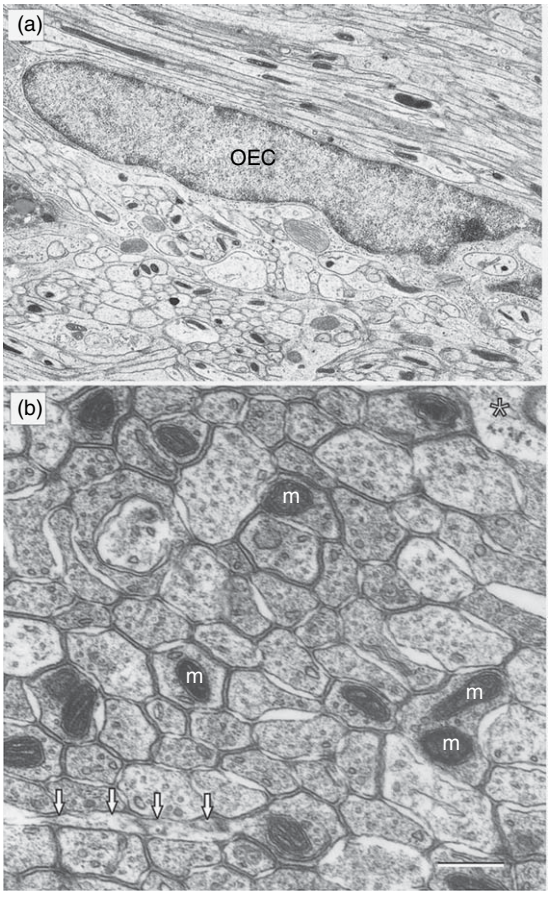

Figure 2 Electron micrographs from the olfactory nerve layer of the olfactory bulb. (a) Low magnification showing both longitudinally and transversely sectioned olfactory sensory neuron axons in the nerve layer. The nucleus (OEC) and some of the surrounding cytoplasm of an olfactory ensheathing cell is in the center of the image. Note that processes extending from the ensheathing cells surround bundles of the axons to form fascicles. (b) Higher magnification of a subset of olfactory sensory neuron axons. Ensheathing cell process (* and arrows) distribute among the axons. The fine structure of the axons includes mitochondria (m) as well as micro- and neurotubules. There is some variability in cross-sectional diameter, but the mean diameter of the olfactory sensory axons approximates 0.2 μm. OEC, olfactory ensheathing cell; m, mitochondria. Calibration bar (shown in b), 1.5 μm in (a) and 0.2 μm in (b).

of heterogeneous OSN axons terminating in the same glomerulus (Zou, D. J. *et al.*, 2004), in the adult all of the axons synapsing within a glomerulus express the same OR (Treloar, H. B. *et al.*, 2002). The specificity and potential mechanisms that influence the coalescence of molecularly homogeneous OSN axons are discussed elsewhere in this volume but may include functional activity as well as adhesion mediated via the expression of ORs in both the axon and growth cone (Feinstein, P. and Mombaerts, P., 2004; Imai, T. *et al.*, 2006; Serizawa, S. *et al.*, 2006).

The interior of the glomerulus contains three primary elements: (1) the arborized axons of the OSNs; (2) the arborized dendritic processes of the projection neurons and glomerular layer neurons; and (3) the processes of glia cells. The interior of the glomerulus is free of cell bodies; rather, both the glia cell and peri/juxtaglomerular cell bodies help to define the perimeter of the glomerulus. At the ultrastructural level, two primary compartments can be identified within the glomerulus (Kasowski, H. J. *et al.*, 1999; Schoppa, N. E. and Westbrook, G. L., 2001). The first contains bundles of dendrites with no or few axons. The second contains numerous axonal boutons and scattered dendritic processes. As will be noted below, local circuit dendrodendritic synapses occur predominately within the dendritic compartment of the glomerulus, while the axodendritic synapses from the OSNs are found predominately within the axonal compartment. Between the intraglomerular compartments, the thin processes of glia cells contribute to segregation and isolation of synaptic circuits. The organization of synapses within the glomerulus will be discussed further below.

4.36.3.3 External Plexiform Layer

The EPL contains scattered populations of cell bodies, including tufted cells and short axon cells, but it is predominately an area of complex neuropil. The apical dendritic processes of projection neurons extend unbranched through the EPL as they target glomeruli where they arborize. In contrast, the secondary dendritic process of the projection neurons extend laterally very broadly in the EPL, in some cases through two-third of the circumference of the olfactory bulb (Mori, K. *et al.*, 1981). The secondary dendrites exhibit some branching, but it appears limited to no more than third or fourth order (Macrides, F. and Schneider, S. P., 1982; Mori, K. *et al.*, 1983; Orona, E. *et al.*, 1984). Also arborizing here are the dendritic processes of the main population of interneurons in the olfactory bulb, the granule cells. The spiny dendrites of these interneurons establish reciprocal dendrodendritic synapses with the secondary dendrites of the projection neurons.

4.36.3.4 Mitral Cell Layer

The mitral cell layer includes the somata of the primary population of projection neurons in the olfactory bulb, the mitral cells. The mitral cells constitute a monolayer in the olfactory bulb, or a sheet that is roughly the thickness of a single mitral cell soma. Additionally, scattered throughout the mitral cell layer are the somata of numerous granule cells. In fact, granule cells make up the majority of cells with somata in the mitral cell layer (Frazier, L. L. and Brunjes, P. C., 1988; Imamura, F. *et al.*, 2006).

4.36.3.5 Internal Plexiform Layer

The IPL includes the axons of projection neurons that will later coalesce to form the lateral olfactory tract, projecting to olfactory cortical targets. The IPL also includes the axons of intrabulbar cells from the juxtaglomerular region that appear to contact homotypic regions on the opposite side of the olfactory bulb (Liu, W. L. and Shipley, M. T., 1994; Belluscio, L. *et al.*, 2002).

4.36.3.6 Granule Cell Layer

The granule cell layer includes organized islets of granule cell somata whose dendrites project into the EPL. Coursing between the islets of granule cells are the axons from the projection neurons that are moving toward the caudal–ventral–lateral aspect of the olfactory bulb where they join to form the lateral olfactory tract. As will be discussed further below, the granule cell layer can be divided into superficial, deep, and intermediate granule cell populations.

4.36.3.7 Subependymal Zone – Rostral Migratory Stream

The innermost region of the olfactory bulb is alternatively identified as a residual of the ventricular extension present during early development, the subependymal zone, or as the terminal region of the rostral migratory stream, the path of migrating neuroblasts, which form new olfactory bulb interneurons in the adult. The rostral migratory stream appears well defined and compact at the caudal pole of the olfactory bulb, as it extends from the olfactory

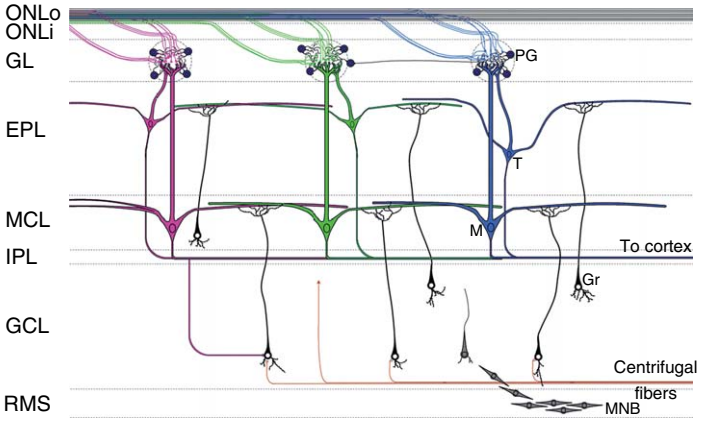

Figure 3 Schematic of the primary cellular organization of the olfactory bulb. Subpopulations of axons, shown in magenta, green, and blue, innervate specific glomeruli based on odor receptor expression. The apical dendritic processes of the projection neurons, mitral, and tufted cells arborize within the glomerulus, as do the dendritic processes of the periglomerular cells. The other primary population of interneurons, granule cells, have their somata located in the granule cell layer and an apical spiny dendrite that arborizes in the external plexiform layer. Axons of periglomerular cells mediate interglomerular actions, while centrifugal axons distribute across the olfactory bulb laminae. ONLo, outer olfactory nerve layer; ONLi, inner olfactory nerve layer; GL, glomerular layer; EPL, external plexiform layer; MCL, mitral cell layer; IPL, internal plexiform layer; GCL, granule cell layer; RMS, rostral migratory stream; PG, periglomerular cell; T, tufted cell; M, mitral cell, Gr, granule cell; MNB, migrating neuroblast.

peduncle, but becomes widely dispersed and indistinct in the rostral pole of the olfactory bulb (Figure 3).

4.36.4 Olfactory Bulb – Cell Populations

4.36.4.1 Projection Neurons

4.36.4.1.1 Mitral cells

Mitral cells are the most prominent population of projection neurons. Their cell bodies, 20–25 μm in diameter, are located in a monolayer, the mitral cell layer. A single apical dendrite (there are some exceptions to this rule) extends from the mitral cell to a single glomerulus where it arborizes extensively including fifth- and sixth-order branches (Price, J. L. and Powell, T. P., 1970c). The numbers are somewhat variable, but approximately 25 mitral cells terminate in each of the 2000 glomeruli found in the mouse olfactory bulb (Royet, J. P. *et al.*, 1998). Also extending from the mitral cell are secondary dendrites that remain restricted to the EPL and can continue for up to two-third of the circumference of the olfactory bulb (Mori, K. *et al.*, 1981). Of interest, the secondary dendrites of mitral cells appear to remain restricted to the deepest portion of the EPL, proximal to the mitral cell layer (Mori, K. *et al.*, 1983; Orona, E. *et al.*, 1984). An axon extends from the basal pole of the mitral cell and joins other axons in the deeper IPL. Myelination occurs quickly, most likely within the IPL. Collateral branches of mitral cell axons appear to extend up into the EPL (Ramon, Y. and Cajal, S., 1911), though the evidence for this is sometimes conflicting (Kishi, K. *et al.*, 1984; Orona, E. *et al.*, 1984). The major axon branches continue on toward the caudal–ventral–lateral aspect of the olfactory bulb where they form the lateral olfactory tract. The axons of the mitral cells distribute broadly throughout olfactory cortical structures.

4.36.4.1.2 Tufted cells

The second population of projection neurons are tufted cells whose diameter is only slightly less than that of mitral cells, approximately 20 μm. Tufted cells are located both proximal to the mitral cell layer (deep tufted cells) and midway in the EPL (middle tufted cells). There is also a population of external tufted cells that are included in the juxtaglomerular population of cells (Pinching, A. J. and Powell, T. P., 1971c), but these appear to have their axons restricted to intrabulbar circuits (Liu, W. L. and Shipley, M. T., 1994; Belluscio, L. *et al.*, 2002). The apical dendrites of the middle and deep tufted cells behave similarly to those of mitral cells – extensive arborization within a single glomerulus. The secondary dendrites, however, differ in that they remain restricted to the most superficial portion of

the EPL, proximal to the glomerular layer (Macrides, F. and Schneider, S. P., 1982; Mori, K. *et al.*, 1983; Orona, E. *et al.*, 1984). The differential distribution of the secondary dendrites of mitral and tufted cells, in the deep and superficial EPL, respectively, coupled with subpopulations of granule cells discussed below, lends credibility to the notion that the mitral and tufted cells may mediate parallel circuits for processing odor information. The axons of the middle and deep tufted cells, like those of the mitral cells, are myelinated, collect initially in the IPL, and then coalesce with the formation of the lateral olfactory tract. Their cortical targets appear to differ from those of mitral cells, with the tufted cells restricted to the most rostral regions of olfactory cortex and the more medial olfactory tubercle (Haberly, L. B. and Price, J. L., 1977).

4.36.4.2 Interneurons

As has been reviewed by a number of authors, there is an almost bewildering array of interneurons found in the olfactory bulb (Schneider, S. P. and Macrides, F., 1978; Shipley, M. T. and Ennis, M., 1996; Shepherd, G. M. *et al.*, 2004; Wachowiak, M. and Shipley, M. T., 2006). Those discussed below represent the major populations whose connectivity and functional properties are best understood.

4.36.4.2.1 Periglomerular cells

The largest population of glomerular layer interneurons are the periglomerular cells. As suggested by their name, the cell bodies, 6–8 μm in diameter, surround and define individual glomeruli. They have brushy and highly branched dendritic processes, often including spine-like extensions. The dendritic process typically arborizes in a single glomerulus, although exceptions in which two or more glomeruli are innervated by separate arbors from a single cell are sometimes seen (Pinching, A. J. and Powell, T. P., 1971c). The axons of periglomerular cells can extend for three to six glomeruli distant from the somata and often branch (Pinching, A. J. and Powell, T. P., 1972; Wachowiak, M. and Shipley, M. T., 2006 for review). The target regions of the periglomerular axons are not always evident, but appear to include extraglomerular apical trunks of projection neurons as well as other periglomerular cells (Pinching, A. J. and Powell, T. P., 1971b). In recent years, it has become increasingly clear that the periglomerular cells may be further subdivided into several subpopulations based on their molecular phenotype and synaptic connections (Kosaka, K. and Kosaka, T., 2005a; Whitman , M. C. and Greer, C. A., 2007).

4.36.4.2.2 External tufted cells

External tufted cells, found predominately at the glomerular layer, EPL border, are slightly larger than the periglomerular cells, approximately 12–15 μm in diameter, with a cell body that is generally elliptical. An apical dendritic process runs parallel to the glomerular layer until it enters and arborizes in a single glomerulus. A secondary dendrite, much shorter than those encountered in mitral or the deep and middle tufted cells (Macrides, F. and Schneider, S. P., 1982), runs parallel and proximal to the glomerular layer. The axons of the external tufted cells extend through the EPL and into the IPL where they travel to a homotypic site on the opposite side of the olfactory bulb (Liu, W. L. and Shipley, M. T., 1994). The external tufted cells may provide a functional link between the two complementary regions in each half of the olfactory bulb that receive the same odor information (Belluscio, L. *et al.*, 2002).

4.36.4.2.3 Short axon cells

Short axon cells in the glomerular layer, located proximal to the nerve layer, are the rarest glomerular layer interneurons. They are slightly larger than periglomerular cells, 8–12 μm in diameter, and have a dendritic arbor that appears to surround the glomeruli, rather than densely innervating them as is seen with the periglomerular cells. Their axons, like those of the periglomerular cells, remain restricted to the juxtaglomerular region. Recent evidence suggests that this may contribute to circuits that include the external tufted cells and periglomerular cells of distant glomeruli.

4.36.4.2.4 Van Gehuchten cells

Short axon cells, Van Gehuchten cells (Schneider, S. P. and Macrides, F., 1978), are the predominate interneurons found in the EPL, and even these are relatively rare. They have a limited dendritic arbor within the EPL and axonal branches that distribute within both the EPL and mitral cell layer where they are thought to contact tufted and mitral cells, respectively.

4.36.4.2.5 Blanes cells

Blanes cells, first described at the end of the nineteenth century (Blanes, T., 1898), have remained largely unknown until recent data suggested they

may interact with olfactory bulb granule cells (Pressler, R. T. and Strowbridge, B. W., 2006). Blanes cells are found throughout the granule cell layer of the olfactory bulb. They have an extensive arborization of spiny dendrites that remain restricted to the granule cell layer. Blanes cell axons remain local with the granule cell layer and are believed to contact the basal dendrites or somata of granule cells. With a cell diameter of approximately 15 μm, Blanes cells are easily distinguished from granule cells.

4.36.4.2.6 Granule cells

The granule cell layer is distinctive due to the arrangement of granule cell somata into rows or islets. Granule cells are small, 8–10 μm in diameter. They have a well-developed apical dendrite that extends into the EPL where it arborizes and becomes heavily invested with dendritic spines. A smaller less arborized basal dendrite is also present that remains restricted to the granule cell layer. Of perhaps greatest interest, the olfactory bulb granule cells are anaxonic; they do not develop an axon (Price, J. L. and Powell, T. P., 1970a). All of the synaptic input and output functions occur via the dendrites. The dendritic spines, also known as gemmules, of the granule cell are somewhat unusual in both receiving and making synapses. Contiguous compartments within the spine are specialized for efferent or afferent function (Rall, W. *et al.*, 1966; Price, J. L. and Powell, T. P., 1970b). In addition, the spine necks are often quite long (>5 μm), and the major axes of the spine head can exceed 2 μm × 5 μm (Woolf, T. B. *et al.*, 1991a; 1991b). The distribution/density of spines is highest throughout the arbor in the EPL, with only an occasional spine seen in the ascending apical dendritic trunk (Price, J. L. and Powell, T. P., 1970a). Granule cells can be divided into at least three subpopulations: (1) those whose cell bodies are located deep within the granule cell layer and whose apical dendritic arbor is limited to the deep EPL, proximal to the mitral cell layer; (2) those whose cell bodies are located more superficially in the granule cell layer and whose dendrites extend unbranched through the deep EPL until they reach the superficial EPL where they arborize extensively; and (3) those whose apical dendrites arborize within both the superficial and deep EPL (Mori, K. *et al.*, 1983; Orona, E. *et al.*, 1983; Greer, C. A., 1987; Imamura, F. *et al.*, 2006). Recalling the differential distribution of the secondary dendrites of mitral and tufted cells (Mori, K. *et al.*, 1983), the organization of the granule cell dendrites suggest that deep granule cells may interact preferentially with mitral cell dendrites while the superficial granule cells interact preferentially with tufted cell dendrites. Other populations of interneurons, such as Blanes cells, Henson's cells and short axon Golgi cells are also found in the granule cell layer but occur at a low frequency and are not as well characterized (Price, J. L. and Powell, T. P., 1970c; Schneider, S. P. and Macrides, F., 1978).

4.36.4.3 Glia

Beginning in the nerve layer, a distinct population of glia are identified, the OEC/glia. These have thin processes that wrap fascicles of OSN axons, beginning deep to the basal lamina in the OE and continuing up to the olfactory bulb glomeruli (Doucette, R., 1991; 1993; Au, W. W. *et al.*, 2002). Several lines of evidence suggest that the olfactory ensheathing glia may contribute to the ability of the OSN axons to successfully extend and innervate glomeruli throughout life (Doucette, R., 1990). Of further interest, the olfactory ensheathing glia have captured the interest of laboratories working on problems such as spinal cord injury where transplants of glia purified from the olfactory nerve appear to promote and improve recovery following injury (Ramon-Cueto, A. *et al.*, 1998; Bartolomei, J. C. and Greer, C. A., 2000).

The shells of the glomeruli are formed, in part, by astrocytes that surround and delineate the surface (Bailey, M. S. and Shipley, M. T., 1993; Chang, C. Y. *et al.*, 2003). Processes extending from their cell bodies distribute within the glomeruli and contribute to the segregation of the axonal and dendritic synaptic compartments (Chao, T. I. *et al.*, 1997).

The EPL, mitral cell layer, and granule cell layer have small populations of astrocytes. It is of interest to point out that many of the synapses within the EPL lack the tight glia wrapping seen elsewhere in the nervous system (Bailey, M. S. and Shipley, M. T., 1993). The rostral migratory stream, however, particularly at the more caudal pole of the olfactory bulb, is defined in part by a compact population of astrocytes that surround and closely interdigitate with the migrating neuroblasts. Much remains to be learned about the properties of this population of glia, but they do appear to contribute to both the migratory dynamics of the neuroblasts and their topographically restricted path (Lois, C. *et al.*, 1996) (Figure 4).

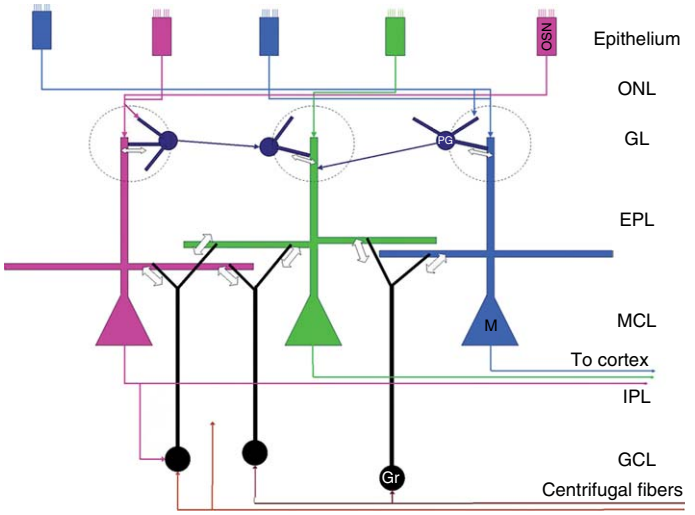

Figure 4 Schematic illustrating primary synaptic interactions in the olfactory bulb. After sorting into specific glomeruli, the axons of the olfactory sensory neurons make excitatory synapses onto the apical dendrites of the projection neurons, mitral, and tufted cells, as well as onto the periglomerular cell dendrites. Intraglomerular circuits also include reciprocal dendrodendritic synapses between the mitral/tufted cell dendrites and the periglomerular cell dendrites. Periglomerular cells can also influence activity in neighboring glomeruli by axodendritic synapses onto mitral/tufted cells and other periglomerular cells. In the external plexiform layer, spiny granule cell dendrites establish reciprocal dendrodendritic synapses with the secondary or lateral dendrites of mitral/tufted cells. Centrifugal axons terminate heavily in the granule cell layer as well as in the external plexiform and glomerular layers of the olfactory bulb. OSN, olfactory sensory neuron; PG, periglomerular cell, M, mitral cell; Gr, granule cell. Arrows indicate the polarity of the synapses – unidirectional or bidirectional.

4.36.5 Olfactory Bulb – Synaptic Organization

4.36.5.1 Glomerular Layer

Our models of synaptic organization in the glomerular layer are becoming increasingly complex as new tools are applied that distinguish between subpopulations of juxtaglomerular neurons and the distribution of their axons and dendritic processes (Chen, W. R. and Shepherd, G. M., 2006; Wachowiak, M. and Shipley, M. T., 2006). Many questions regarding the specificity of synapses within and between glomeruli remain unanswered. The synaptic organization discussed below reflects our current understanding of the basic model for which most information has been compiled.

As was noted earlier, the neuropil of the glomeruli can be divided into two distinct compartments: (1) the axonal compartment which contains the terminal boutons of the OSN axons and scattered dendritic processes; and (2) the dendritic compartment which contains bundles of closely apposed dendrites. This segregation is the foundation for the isolation of primary afferent versus local circuit synapses in the glomerulus (Schild, D. and Riedel, H., 1992; Kasowski, H. J. *et al.*, 1999) (Figure 5).

The axons of the OSNs do not branch until they innervate a glomerulus. As they enter the glomerulus, primarily at the boundary of the ONL and glomerular layer, the axons are tightly bundled but within the glomerular neuropil they separate and arborize (Pinching, A. J. and Powell, T. P., 1971a). Each axon establishes only a limited number of synapses; usually no more than 10–15 Gray Type I asymmetrical synapses with the dendrites of projection neurons or interneurons. The OSN axon specializations include both *en passant* varicosities and terminal boutons. Both specializations are filled with many small spherical vesicles, characteristic of glutamate, and often appear quite electron dense. Single dendritic processes are often seen surrounded by multiple OSN axon boutons, each of which is making a synapse. Although the distribution of the terminal boutons and *en passant* specialization of the axons is spatially restricted within the glomerulus, it is not known if their synapses converge onto the dendrites of the same cell or diverge and broadly synapse with the dendrites of many cells. Of interest, the axodendritic synapses from the OSN axons are found predominately toward the thinner tips/branches of the dendrites within the glomerulus (Pinching, A. J. and Powell, T. P., 1971a; Shepherd, G. M., 1972).

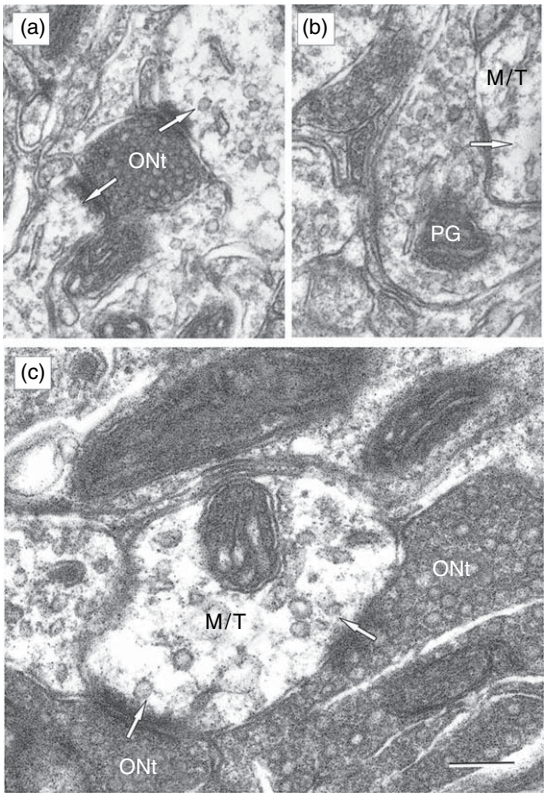

Figure 5 Electron micrographs of the primary synaptic appositions in the glomeruli of the olfactory bulb. In (a) and (c) olfactory sensory axon terminal boutons (ONt) are seen making asymmetrical synapses onto pale dendrites tentatively identified as mitral/tufted (M/T). The ONt is characterized by its electron dense appearance and clustering many small spherical vesicles adjacent to the presynaptic membrane. The target dendrite is recognized by the asymmetrical thickening of the postsynaptic membrane. In (b) a periglomerular cell (PG) is seen making a symmetrical synapse on an M/T dendrite. The PG dendrite has slightly elliptically shaped vesicles, and the pre- and postsynaptic membrane are symmetrical. Arrows indicate the polarity of the synapses. ONt, olfactory sensory axon terminal bouton; PG, periglomerular cell dendrite; M/T, mitral/tufted cell dendrite. Calibration bar (shown in c), 160 nm in (a) and 200 nm in (b) and (c).

Within the dendritic compartment of the glomerulus, the tightly bundled dendrites of the projection neurons and periglomerular cells establish reciprocal dendrodendritic synapses. The excitatory Gray Type I dendritic synapse is characterized by a small collection of spherical vesicles closely apposed to the dendritic membrane of a mitral or tufted cell. The apposed process, a periglomerular cell dendrite, has a thick postsynaptic specialization. Although the reciprocal synapse from the periglomerular cell to the mitral/tufted cell is occasionally seen in the same plane of section, it is much more common for them to be separated and recognized as reciprocal connections only following serial sectioning and reconstruction. The periglomerular synapse can be found in both spine-like processes or in the shafts of periglomerular cell dendrites. The inhibitory Gray Type II synapse from the periglomerular cell dendrite to the mitral/tufted cell dendrite includes a collection of vesicles, often elliptical in shape and adjacent to the presynaptic membrane. The specialization on the postsynaptic membrane is a thickening symmetrical to that seen on the presynaptic membrane. In contrast to the location of the primary afferent axodendritic synapses on the finer terminal branches of the dendrites, the Gray Type II synapses are most often found on larger trunks and at branch points (Pinching, A. J. and Powell, T. P., 1971a; Shepherd, G. M., 1972). This is consistent with the spatial distribution of excitatory and inhibitory synapses described in cortex and suggests that the inhibitory synapse can function as a gatekeeper that modulates excitatory inputs.

Recent evidence suggests that external tufted cells and glomerular layer short axon cells may also contribute to dynamic regulation of center-surround inhibition among glomeruli (Aungst, J. L. *et al.*, 2003). The short axon cells are believed to influence glomeruli up to 500 µm distant. Activation of the short axon cells occurs via a direct input of the OSN axons onto external tufted cells which, in turn, excite the short axon cells. While the full details of this and other glomerular circuits remain to be established, it is clear that the glomerular layer includes the circuitry for complex processing and integration of odor stimuli.

The terminals of centrifugal axons are also found in both the glomerular neuropil and juxtaglomerular space. These arise from several sources including the anterior olfactory nucleus, horizontal limb of the diagonal band, the raphe nucleus, and the locus coeruleus. While it is evident that these circuits help to modify intraglomerular information processing, their full nature has yet to be resolved (e.g., Wachowiak, M. and Shipley, M. T., 2006).

4.36.5.2 External Plexiform Layer

The EPL is the site of the most well-studied reciprocal dendrodendritic synapse in the mammalian nervous system: the mitral/tufted granule cell dendritic spine synapse (Hirata, Y., 1964; Andres, K. H., 1965; Rall, W. *et al.*, 1966; Landis, D. M. *et al.*, 1974;

Jackowski, A. *et al*., 1978). The basic features are similar to those described about for the glomerular local circuits but, in the EPL the reciprocal synapse can often be seen in a single plane since the specialization is restricted to the granule cell spine (gemmule). The secondary dendrites of mitral/tufted cells can be quite large (>4 μm in cross section), and the clusters of spherical vesicles associated with the presynaptic specialization of the Gray Type I synapse often appear quite isolated. At the level of the electron microscope, there are no obvious structural determinants that regulate the clustering of vesicles, although recent evidence shows that vesicle-associated proteins regulating clustering, mobilization, and recycling are present in these presynaptic dendrites (Greer laboratory, unpublished observations). The apposed granule cell spine has an asymmetric thickening immediately opposite the clustering of vesicles within the mitral/tufted cell dendrite (Figure 6).

The granule cell spine, in addition to the asymmetric postsynaptic membrane specialization, appears somewhat unique. It is filled with a large cluster of elliptical vesicles that are closely apposed to the symmetrical membrane thickenings characteristic of the Gray Type II synapse. Often the transition in the structure of the membrane between the asymmetrical postsynaptic thickening and the presynaptic symmetrical thickening is abrupt; the two specializations do not always appear to be separated by nonspecialized membrane leading to speculation about the independence of these two synapses. The granule cell dendritic spine, as was noted earlier, often has a very thin and long neck. Nevertheless, mitochondria can be

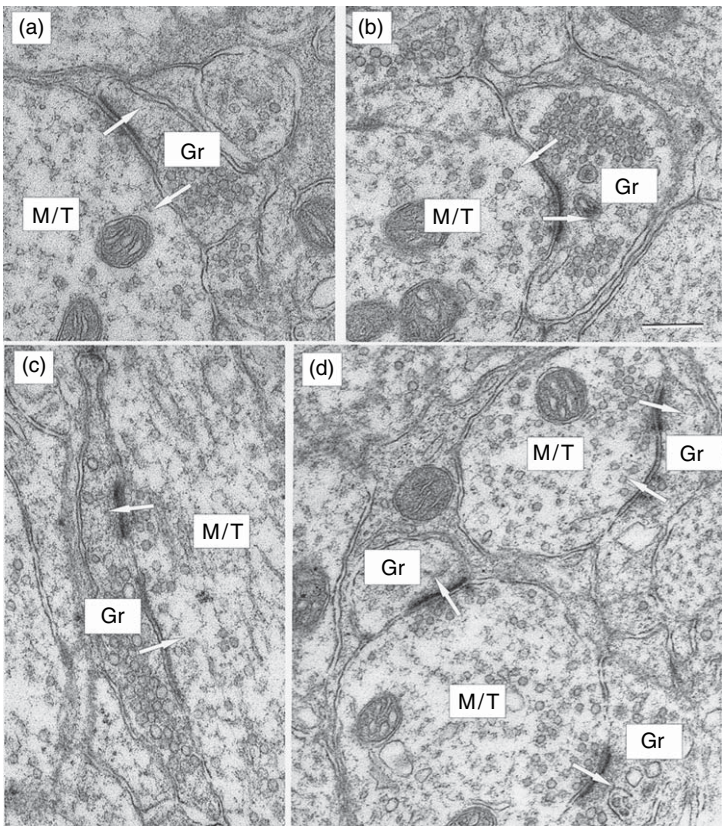

Figure 6 Electron micrographs of the reciprocal dendrodendritic synapses in the external plexiform layer of the olfactory bulb. In (a)–(d), examples of reciprocal dendrodendritic synapses between mitral/tufted (M/T) dendrites and granule cell spines (Gr) are shown. The asymmetrical synapse from the M/T to the Gr is characterized by a smaller collection of vesicles adjacent to the presynaptic membrane of the M/T dendrite and an asymmetrical thick postsynaptic specialization on the Gr membrane. The reciprocal symmetrical synapse is characterized by a larger collection of elliptical or heterogeneous vesicles and a symmetrical thickening of the pre- and postsynaptic membranes. Arrows indicate the polarity of the synapses. M/T, mitral/tufted cell dendrite; Gr, granule cell spine. Calibration bar (shown in b), 200 nm.

found extending from the parent dendrite into the spine head, as does smooth endoplasmic reticulum (Cameron, H. A. *et al.*, 1991; Woolf, T. B. *et al.*, 1991a). Reports of free and polyribosome clusters are also common. As was found for the mitral/tufted cell dendrites, the granule cell spines exhibit an array of vesicle-associated proteins consistent with the role as a presynaptic compartment. Given the immediate proximity of the reciprocal synapses found in the EPL, one can argue that this is the smallest microcircuit found in the nervous system.

4.36.5.3 Mitral Cell Layer

The ascending dendrites of granule cells also establish somatodendritic synapses with mitral cell bodies in the mitral cell layer. The features of these appear indistinguishable from those described above for the dendrodendritic synapses. Although it seems reasonable that tufted cell bodies may also be involved in somatodendritic synapses with granule cells in the EPL, none have been described.

4.36.5.4 Internal Plexiform Layer

Immunohistochemical and electron microscopy studies suggest that the collaterals of external tufted cells make synapses onto the ascending dendrites of granule cells within the IPL (Liu, W. L. and Shipley, M. T., 1994). More recent studies suggest that these connections are topographically organized so that the glomeruli on the opposite sides of the olfactory bulb that receive input from the same OR are synaptically linked via the external tufted cell circuit (Belluscio, L. *et al.*, 2002; Lodovichi, C. *et al.*, 2003; Marks, C. A. *et al.*, 2006).

4.36.5.5 Granule Cell Layer

The basal dendrites of the granule cells in the granule cell layer receive synaptic input from a variety of sources (Price, J. L. and Powell, T. P., 1970a). Axon collaterals from mitral and tufted cells form asymmetric synapses on granule cell basal dendrites as do axons from the anterior olfactory nucleus, anterior commissure, olfactory cortex, horizontal limb of the diagonal band (Carson, K. A., 1984; Shipley, M. T. and Adamek, G. D., 1984), the locus coeruleus (McLean, J. H. *et al.*, 1989; McLean, J. H. and Shipley, M. T., 1991), and the raphe nucleus (McLean, J. H. and Shipley, M. T., 1987). While their specific functions and role in modulating information processing in the olfactory bulb are not entirely clear, it is evident that the synaptic actions of these circuits will activate the granule cells and, in turn, their dendrodendritic circuits within the EPL. Thus, as is typical of most sensory systems, centrifugal and feedback circuits contribute to the flow of information through the olfactory bulb.

4.36.5.6 Electrical Synapses in the Olfactory Bulb

Gap junctions were long known to be the structural correlates of electrical coupling between cells (Rash, J. E. *et al.*, 1998); however, accumulating evidence that electrical coupling can confer unique properties to neural circuits has lately increased the interest in their distribution and properties (Rela, L. and Szczupak, L., 2004). As in other regions of the brain, gap junctions have been found in the olfactory bulb. In the ONL, gap junctions are abundant in the olfactory ensheathing glia, but seem to be absent from OSN axons (Rash, J. E. *et al.*, 2005). Within glomeruli, gap junctions are found between mitral/tufted dendrites, as well as between mitral/tufted cell dendrites and periglomerular cell dendrites, perhaps complementing the reciprocal dendrodendritic synapses (Pinching, A. J. and Powell, T. P., 1971b; Christie, J. M. *et al.*, 2005; Kosaka, T. and Kosaka, K., 2005b; Rash, J. E. *et al.*, 2005). Consistent with an interaction between chemical and electrical synapses, in the EPL examples of mixed synapses that include both gap junctions and conventional dendrodendritic synapses are reported between mitral/tufted cell secondary dendrites and granule cell spines. In the mitral cell layer, somatodendritic synapses between mitral and granule cells may also involve a combination of chemical and electrical components, as suggested by the identification of structures compatible with gap junctions in mitral/tufted cell perikarya (Miragall, F. *et al.*, 1996). Finally, gap junction coupling between granule cell bodies represents a plausible mechanism to synchronize the activity of clusters of these inhibitory interneurons (Reyher, C. K. *et al.*, 1991; Gibson, J. R. *et al.*, 1999; Galarreta, M. and Hestrin, S., 2001).

4.36.6 Lateral Olfactory Tract and Olfactory Cortex

The lateral olfactory tract forms at the caudal–lateral–ventral aspect of the olfactory bulb with the

coalescence of mitral and tufted cell axons following their passage through the IPL and islets of granule cells. Because the axons are myelinated, in gross dissection the tract appears white. As the tract proceeds caudally, it moves to a more ventral position. Within the tract, the myelinated profiles of the projection neuron axons have a bimodal distribution for cross-sectional diameter. The larger profiles (~1.42 μm) are believed to arise from mitral cells while the smaller profiles (~1.14 μm) are axons from the middle and deep tufted cells (Price, J. L. and Sprich, W. W., 1975; Bartolomei, J. C. and Greer, C. A., 2000). In cortex, the axons exit the lateral olfactory tract and enter layer Ia where they make Gray Type I excitatory synapses with the spiny apical dendrites of both layer II and layer III pyramidal cells (Westrum, L. E., 1975; Wouterlood, F. G. and Nederlof, J., 1983; Schwob, J. E. and Price, J. L., 1984). In cortex, the distribution of the projection neuron axons is complex and remains somewhat controversial (Wilson, D. A. *et al.*, 2006). One line of evidence from functional studies suggest that the axons have terminal fields that maintain the molecular specificity of OR input first established at the level of the glomerulus (Zou, Z. *et al.*, 2001; 2005). This is also consistent with recent analyses using pseudorabies virus to characterize olfactory bulb – cortical topography (Willhite, D. C. *et al.*, 2006). Earlier retrograde tracing, however, suggested that axon collaterals of single mitral cells diverged broadly throughout the rostral–caudal extent of cortex (Haberly, L. B. and Price, J. L., 1977; Scott, J. W. *et al.*, 1980; Luskin, M. B. and Price, J. L., 1982; Zou, Z. *et al.*, 2001; Fukushima, N. *et al.*, 2002). Further discussion of the synaptic organization of piriform cortex is beyond the scope of this chapter other than to comment that it is complex and includes feedback circuits both within cortex as well as centrifugals to the ipsilateral olfactory bulb and to the contralateral olfactory pathway via the anterior commissure (de Olmos, J. *et al.*, 1978; Haberly, L. B. and Price, J. L., 1978a; 1978b; Luskin, M. B. and Price, J. L., 1983a; 1983b). New studies will help to clarify the complex relationship between the olfactory bulb and cortex including the organization of the cortically derived centrifugal axons that return to the bulb.

4.36.7 Adult Neurogenesis and the Olfactory Bulb

While it has been recognized for some time that the OSNs turn over and are replaced by a population of basal cells in the OE, the magnitude of adult neurogenesis of olfactory bulb neurons has been recognized relatively recently (Altman, J., 1969; Kaplan, M. S. and Hinds, J. W., 1977; Lois, C. and Alvarez-Buylla, A., 1994). Several excellent reviews are available that summarize our current understanding of neurogenesis within the subventricular zone, the migration of neuroblasts via the rostral migratory stream into the olfactory bulb, and the ensuing differentiation of the migrating cells into granule and periglomerular cells (Alvarez-Buylla, A. and Garcia-Verdugo, J. M., 2002; Lennington, J. B. *et al.*, 2003; Doetsch, F. and Hen, R., 2005; Lledo, P. M. and Saghatelyan, A., 2005; Lledo, P. M. *et al.*, 2006). In the context of the plasticity of olfactory bulb synaptic circuits, many questions remain about the mechanisms influencing cellular loss and replacement among these populations of interneurons and the determinants of newly established synapses (Whitman, M. C. and Greer, C. A., 2007). It may be that the ongoing turnover of these populations of interneurons is a solution to the dynamic and transient nature of odor stimuli – an approach to nervous system plasticity that may function in concert with other mechanisms of synaptic plasticity including long-term potentiation and long-term depression (Figure 7).

4.36.8 Summary

The molecular, cellular, and synaptic organization of the olfactory bulb continue to pose significant challenges in understanding the dynamic nature of this structure and how the organization of the system may contribute to odor coding/processing. The advent of powerful molecular tools toward the end of the twentieth century has resulted in significant new insights into the complex wiring of the olfactory bulb, but many questions remain unanswered. Among the challenges that remain are understanding the developmental events that underlie the specificity of afferent axon convergence as well as the extraordinary precision of local synaptic circuits in the olfactory bulb and their ongoing remodeling.

Acknowledgments

Work from the author's laboratory has been generously supported by grants from NIH-NIDCD and NIH-NIA. The authors express the appreciation to other members of the laboratory for helpful discussions.

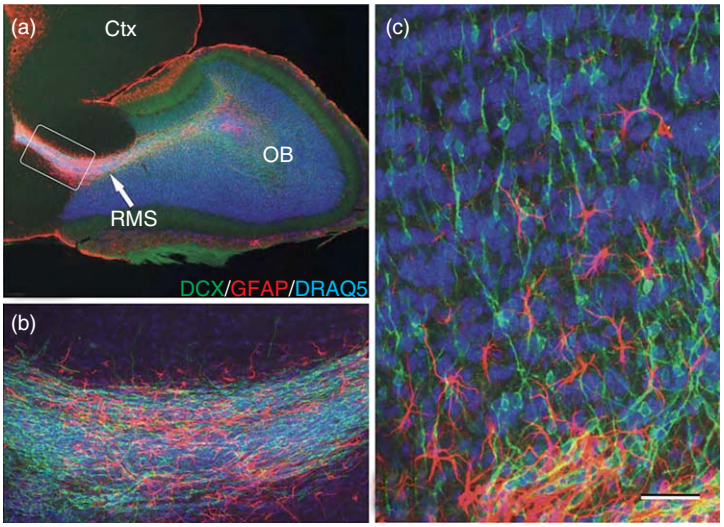

Figure 7 The rostral migratory stream and migrating neurons in the olfactory bulb. In (a), a sagittal section of the rostral brain and olfactory bulb shows the rostral migratory stream (RMS) as it travels from the subventricular zone, through the olfactory peduncle, and into the olfactory bulb. Doublecortin (DCX) staining shows the migrating neuroblasts while staining for glial fibrillary acitic protein (GFAP) shows the glial cells that surround the RMS. DRAQ5 identifies nuclei. In (b), the boxed area in (a) is shown at higher magnification. The density of GFAP-positive glia surrounding the chains of DCX-positive migrating neuroblasts is more apparent. In (c), the DCX-positive cells are exiting the RMS (bottom of image) and beginning to either differentiate as granule cells or migrate to the glomerular layer and differentiate into periglomerular cells. Ctx, cortex; RMS, rostral migratory stream; OB, olfactory bulb. Calibration bar (shown in c), 300 μm in (a); 100 μm in (b); and 40 μm in (c).

field potentials Extracellularly recorded voltages representing summed currents from a population of neurons.
gabazine A $GABA_A$ receptor antagonist.
ZD 7288 A blocker of Ih channels.
4-AP A blocker of A-type potassium channels (I_A).

4.37.1 Overview of Main Olfactory Bulb Circuitry

4.37.1.1 Projections of Olfactory Receptor Neurons to Main Olfactory Bulb

As discussed elsewhere (Chapter Signal Transduction in the Olfactory Receptor Cell), odors are transduced by olfactory receptor neurons (ORNs), giving rise to action potentials. The action potentials propagate along the axons of ORNs – the olfactory nerve (ON) fibers. These fibers form bundles which then collect as groups of fascicles, pass through the cribriform plate, and synapse in the main olfactory bulb (MOB). Within the MOB, ON axons terminate and synapse with neural elements in the glomerular layer (GL). Based on anatomical considerations (high packing density of unmyelinated axons), it has been speculated that ephaptic interactions (current spread through the extracellular space) might synchronize ON fibers. Computational modeling studies (Bokil, H. *et al.*, 2001) suggest that spikes in a single ON axon evoke spikes in adjacent axons, thus leading to synchronous firing of a large number of axons. These findings suggest that ephaptic interactions among neighboring axons may synchronize spikes among ON fibers converging on the same glomerulus.

ORNs expressing the same odorant receptor project to one or two glomeruli located on the medial and/or lateral side of each MOB (Figure 1; Ressler, K. J. *et al.*, 1993; 1994; Vassar, R. *et al.*, 1994; Mombaerts, P. *et al.*, 1996; Wang, F. *et al.*, 1998; Potter, S. M. *et al.*, 2001; Treloar, H. B. *et al.*, 2002). Studies in transgenic animals showed that this projection pattern is topographically fixed across animals. That is, the same glomeruli identified in different mice receive inputs from the same restricted population of ORNs bearing the same receptor (Mombaerts, P. *et al.*, 1996; Wang, F. *et al.*, 1998; Potter, S. M. *et al.*, 2001; Treloar, H. B. *et al.*, 2002). Rough calculations confirm an approximately 1:2 ratio between the number of different types of receptors (~1000) and the total number of glomeruli (~1800) in mice.

ORNs utilize glutamate as their primary neurotransmitter (Sassoe-Pognetto, M. *et al.*, 1993). Carnosine, a soluble dipeptide, is uniquely expressed in high concentrations in mammalian ORNs, and it is present in ON axon terminals in the GL (Ferriero, D. and Margolis, F. L., 1975; Margolis, F. L., 1980; Biffo, S. *et al.*, 1990). Carnosine colocalizes with glutamate in the ON axon terminals (Sassoe-Pognetto, M. *et al.*, 1993), and it satisfies criteria for neurotransmitter candidacy, including (1) carnosine synthetic and degradative enzymes are present in ORNs; (2) the peptide is released by depolarization in a Ca^{2+}-dependent manner in ON synaptosomes; (3) high-affinity binding sites for carnosine are present in the GL (Ferriero, D. and Margolis, F. L., 1975; Margolis, F. L., 1980; Burd, G. D. *et al.*, 1982; Rochel, S. and Margolis, F. L., 1982; Margolis, F. L. *et al.*, 1983; Margolis, F. L. and Grillo, M., 1984; Margolis, F. L. *et al.*, 1985; 1987; Biffo, S. *et al.*, 1990). Zinc and copper are also present in high concentrations in ON axon terminals (Biffo, S. *et al.*, 1990). The potential neuromodulatory roles of carnosine, zinc, and copper are discussed below.

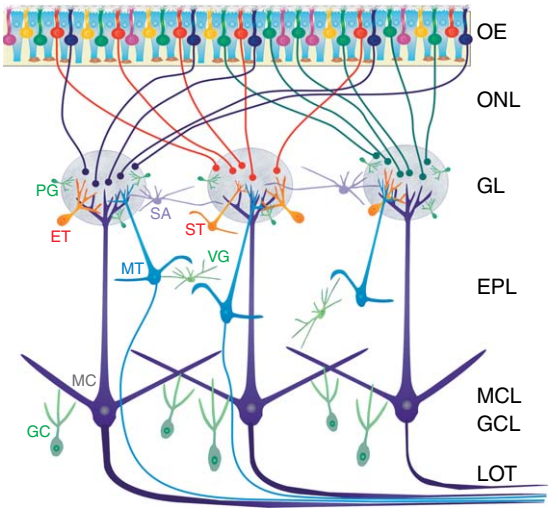

Figure 1 Schematic illustration of the basic circuitry of the main olfactory bulb (MOB) including the projections of olfactory receptor neurons (ORNs) from the olfactory epithelium (OE) to the glomerular layer (GL). Note that ORNs expressing different odorant receptor genes (shown as blue, red, or green cells) are interspersed and widely distributed, yet the axons of ORNs expressing the same odorant receptor gene converge onto the same glomerulus (or pairs of medial and lateral glomeruli) in the GL. Axons of ORNs travel in the olfactory nerve layer (ONL) and synapse in the GL on the dendrites of mitral cells (MC), tufted cells (external tufted cell, ET; middle tufted cell, MT), and generic juxtaglomerular (JG) neurons, which include periglomerular (PG) cells, ET cells, and short axon (SA) cells. SA cells interconnect different glomeruli. There are serial and reciprocal synapses between the apical dendrites of mitral/tufted cells and the processes of JG neurons. Superficial tufted (ST) cells are located in the superficial EPL or at the GL–EPL border. The lateral dendrites of mitral/tufted cells form serial and reciprocal synapses with the apical dendrites of granule cells (GC) in the EPL. The majority of GCs are concentrated in the GC layer (GCL) but many lie within the MCL. The axons of mitral/tufted cells project locally to GCs (not shown) and also to primary olfactory cortex via the lateral olfactory tract (LOT). The bulb also contains other populations of interneurons neurons, including the Van Gehuchten (VG) cells within the EPL.

4.37.1.2 MOB Circuitry

The MOB in rodents is situated at the rostral pole of the cranial cavity, and it is connected to the frontal cortex by a slender peduncle. The bulb can be thought of as a cylinder composed of distinct layers or laminae that are concentrically organized. These layers, from superficial to deep, are the ON layer (ONL), GL, external plexiform layer (EPL), mitral cell layer (MCL), internal plexiform layer (IPL), granule cell layer (GCL), and the ependymal layer (Figure 1). The ONL consists of ON axons and glial cells (Cajal, R. S. Y., 1911a; 1911b; Pinching, A. J. and Powell, T. P., 1971b; Doucette, R., 1989). Deep to the ONL, the GL is comprised of neutropil-rich ovoid structures – the glomeruli – each of which is surrounded by a shell of small neurons and glia. Within the glomeruli, ON axons form synapses with mitral and tufted cells, as well as with the intrinsic neurons of the GL – the juxtaglomerular (JG) cells. Adjacent glomeruli are somewhat isolated from each other by astrocytes residing in the glomerular shell (Bailey, M. S. and Shipley, M. T., 1993). The EPL lies beneath or deep to the glomeruli, and it primarily consists of dense neuropil formed by the dendrites of mitral cells and GCs that ascend from the MCL and GCL, respectively. The EPL also contains several subtypes of tufted cells and intrinsic interneurons. The dominant feature of the EPL is nevertheless the extensive dendrodendritic synapses between mitral/tufted cells and GCs. Deep to the EPL, the MCL is a thin layer that contains the somata of mitral cells, as well as numerous GCs (Cajal, R. S. Y., 1911a; 1911b). Together with tufted cells, mitral cells are the major class of output cells of the bulb. They extend a single apical dendrite into the GL, where it arborizes extensively throughout much of a single glomerulus (Figure 1). The apical dendrites are synaptically contacted by ON terminals (Price, J. L. and Powell, T. P. S., 1970a; Shepherd, G. M., 1972). The secondary or lateral dendrites of mitral cells ramify in the EPL where they form dendrodendritic synapses with dendrites of GCs. Mitral/tufted cell axons terminate within the bulb in the IPL and GCL (Mori, K. *et al.*, 1983; Price, J. L. and Powell, T. P. S., 1970c), or exit the MOB and innervate a number of olfactory-related brain regions collectively known as the primary olfactory cortex (POC). Deep to the MCL, the IPL is the relatively thin layer with a low density of cells. The GCL is the deepest neuronal layer in the bulb, and it contains the largest number of cells. Most of the neurons of the GCL are the GCs, but there are also small numbers of Golgi cells, Cajal cells, and Blanes cells. The GCs are inhibitory GABAergic cells that form dendrodendritic synapses with mitral/tufted cells in the EPL.

4.37.2 Neurophysiology of the Glomerular Layer

4.37.2.1 Neurophysiological Properties of Glomerular Layer Neurons

The neurons of the GL are classified into three cell types, which include: (1) periglomerular (PG) cells,

(2) external tufted (ET) cells, and (3) short axon (SA) cells (Golgi, C. 1875; Van Gehuchten, L. E. and Martin, A., 1891; Blanes, T., 1898; Cajal, R. S. Y., 1911a; 1911b; Pinching, A. J. and Powell, T. P., 1971a; 1971b; 1971c; 1972b; 1972c). Collectively, the intrinsic neurons of the GL are referred to as JG cells. The term JG is also used here with regard to cited studies in which the subtype of glomerular neuron was not specified. The morphology and features of these cells are only briefly reviewed here as more detailed descriptions are available (Hayar, A. *et al.*, 2004a; 2004b).

4.37.2.1.1 ET cells

These are relatively large (10–15 μm) cells that are dispersed in the JG regions surrounding/deep to the glomeruli (Figures 1 and 2). Most have one apical dendrite that arborizes extensively throughout one glomerulus (Pinching, A. J. and Powell, T. P., 1971a; Hayar, A. *et al.*, 2004a; 2004b). Rarely, ET cells have two or three apical dendrites that ramify in different glomeruli. Most ET cells have secondary or lateral dendrites that extend in the superficial EPL. Some ET cells have axons that appear to synapse with PG cells or SA cells, or more infrequently project out of MOB (Pinching, A. J. and Powell, T. P., 1971a). ET cells are somewhat similar to tufted cells of the EPL and to mitral cells, but growing evidence suggests that all tufted cell subtypes exhibit distinct anatomical and physiological properties.

The most distinctive physiological feature of ET cells *in vitro* is their spontaneous rhythmical bursting (Hayar, A. *et al.*, 2004a; 2004b; 2005) (Figure 2). JG cells with burst characteristics have been reported *in vivo* (Getchell, T. V. and Shepherd, G. M., 1975; Wellis, D. P. and Scott, J. W., 1990). However, because of the difficulty of recording small JG neurons *in vivo*, the identity of these cells and the basis of their bursting behavior remained unknown. The rhythmical burst-firing mode was characteristic of morphologically confirmed ET neurons (Hayar, A. *et al.*, 2004a). By contrast, PG and SA cells do not spontaneously generate spike bursts nor can they be induced to do so by intracellular current injections (Figure 2). Each ET cell bursts at its own characteristic frequency. As a population, ET cell burst frequencies range from ~1 to 8 Hz, with a mean of 3.3 ± 0.18 bursts/s. This range overlaps with the theta frequency range (2–12 Hz) prominent in oscillatory neural activity in the rodent olfactory network (see Oscillations and Synchrony in Main Olfactory Bulb); the theta range includes components related to low frequency (1–3 Hz) passive sniffing as well as a higher frequency component (5–10 Hz) characteristic of active investigative sniffing (Adrian, E. D., 1950; Welker, W. I., 1964; Macrides, F. *et al.*, 1982; Eeckman, F. H. and Freeman, W. J., 1990; Kay, L. M. and Laurent, G., 1999; Kay, L. M., 2003). ET cells also receive spontaneous bursts of inhibitory postsynaptic currents (IPSCs) from PG cells (Hayar, A. *et al.*, 2005). ON stimulation evokes an excitatory postsynaptic current (EPSC) in ET cells that is followed by IPSC bursts (Hayar, A. *et al.*, 2005). Both the spontaneous and ON-evoked IPSCs in ET cells are driven primarily by activation of AMPA receptors.

Several lines of evidence indicate that bursting is an intrinsic property of ET cells. First, bursting deteriorates rapidly after establishment of whole-cell recording mode. This pronounced rundown of bursting may explain the low reported incidence of spontaneous bursting in JG cells in some whole-cell recording studies (Bardoni, R. *et al.*, 1995; Puopolo, M. and Belluzzi, O. 1996; McQuiston, A. R. and Katz, L. C., 2001). The rundown of bursting could be due to intracellular dialysis of an intracellular messenger important to maintain spontaneous activity (Alreja, M. and Aghajanian, G. K., 1995). Additional evidence in support of the intrinsic mechanism for bursting are the findings that: (1) burst frequency is voltage dependent and (2) bursting persists in blockers of glutamate and $GABA_A$ receptors. This eliminates the possibility that bursting is driven by glutamatergic input from the ON, glutamatergic dendrodendritic interactions among ET cells and/or mitral cells, or by disinhibition (Aroniadou-Anderjaska, V. *et al.*, 1999b; Isaacson, J. S., 1999; Carlson, G. C. *et al.*, 2000; Friedman, D. and Strowbridge, B. W., 2000; Salin, P. A. *et al.*, 2001; Schoppa, N. E. and Westbrook, G. L., 2001). Moreover, spontaneous bursting was not blocked by Cd^{2+}, which suppresses Ca^{2+}-dependent neurotransmitter release, ruling out the potential involvement of other neurotransmitters. Depolarizing current injections evoke in ET cells a low-threshold Ca^{2+} spike (LTS) that was eliminated by the Ca^{2+} channel blockers, Cd^{2+} and Ni^{2+} (McQuiston, A. R. and Katz, L. C., 2001; Hayar, A. *et al.*, 2004a). This suggested that the LTS might generate ET cell bursting. However, this is unlikely for several reasons. First, bursting in ET cells persisted after the LTS was blocked. Second, ET cell bursting was abolished by extracellular TTX or by intracellular QX-314, whereas the LTS persisted. Third, the activation threshold of the LTS (−38 mV) was approximately 15 mV more depolarized than the membrane potential from which bursting arises, on average −53 mV. Ca^{2+} may modulate bursting as

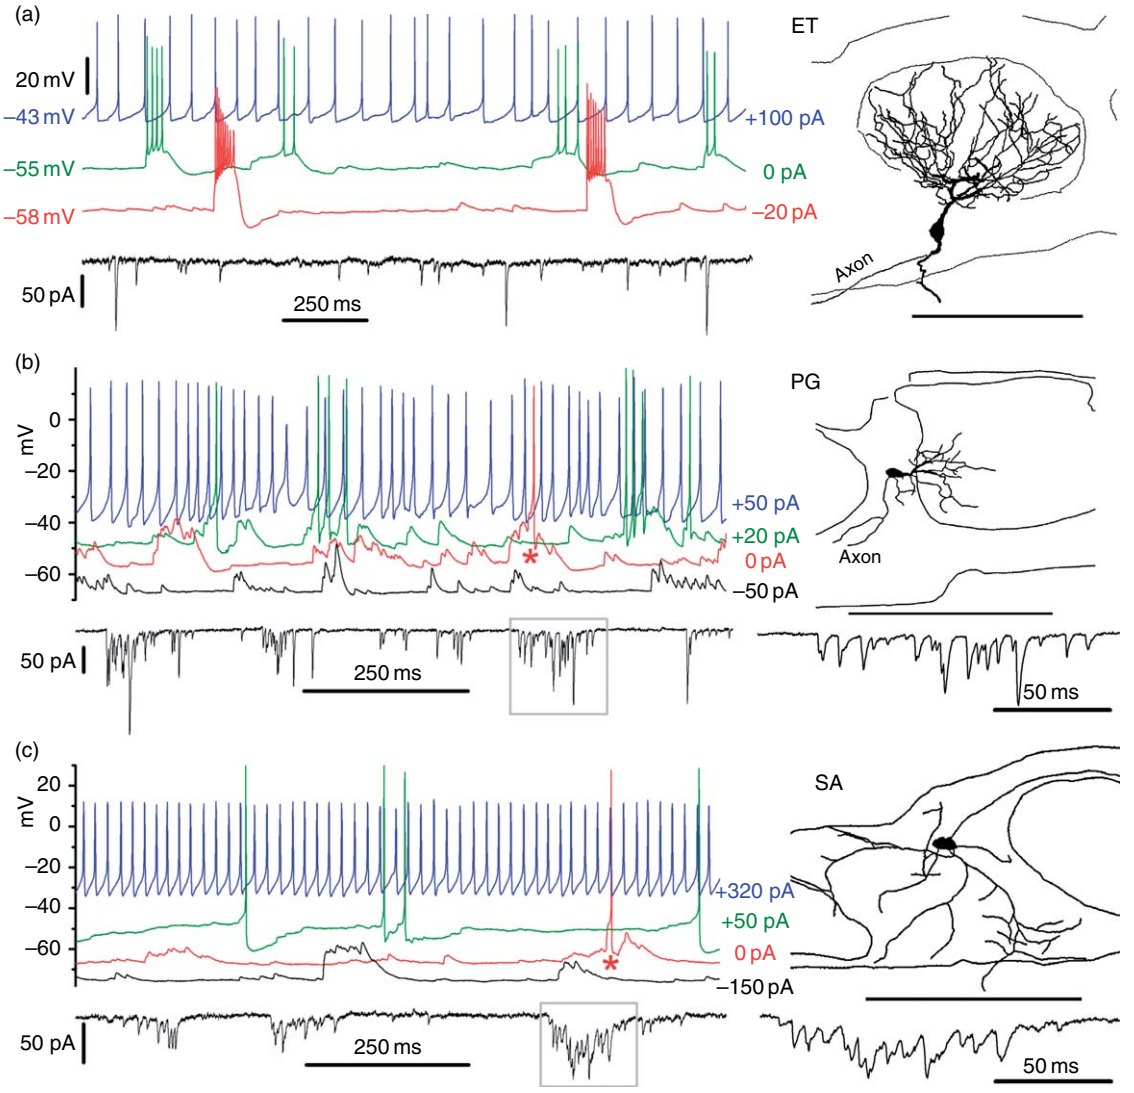

Figure 2 External tufted (ET) cells spontaneously generate rhythmic spike bursts, whereas periglomerular (PG) and short axon (SA) cells receive spontaneous bursts of excitatory synaptic input. Panels (a), (b), and (c) show the typical electrophysiological and morphological features of an ET, a PG, and a SA cell, respectively. The ET cell has highly branched tufted dendrites that ramify throughout a single glomerulus. The PG cell has relatively small soma and one to three relatively thick primary dendritic shafts that give rise to thinner branches ramifying within a subregion of a single glomerulus. The SA cell has several poorly branched dendrites that extended into or between two and four glomeruli. Scale bars below drawings, 100 μm. Current clamp recordings show resting spontaneous activity and effects of current injections. At rest (0 pA), the ET cell generates spontaneous bursts of spikes, whereas the PG and SA cells receive spontaneous bursts of EPSPs and generates spikes infrequently (asterisks). Bottom traces in a, b, and c show voltage-clamp recordings (holding potential = −60 mV) of spontaneous EPSCs in the same cells; regions enclosed in the box in b and c are shown at faster timescale at right. Note the bursting pattern of EPSCs in the PG and SA cells. Adapted from Hayar, A., Karnup, S., Ennis, M., and Shipley, M. T. 2004b. External tufted cells: a major excitatory element that coordinates glomerular activity. J. Neurosci. 24, 6676–6685, with permission from The Society for Neuroscience.

Ca^{2+} channel blockers prolonged burst duration (Hayar, A. *et al.*, 2004a). Ca^{2+} channel blockers also increased the interburst interval, but this could be due to a charge screening effect. Moreover, ET cells have a hyperpolarization-activated cation conductance (Ih) that is prominent at resting membrane potential (Figure 3). Ih current was found in all JG cells (Cadetti, L. and Belluzzi, O., 2001). However, other results (Hayar, A., unpublished observations) indicate that Ih is very strong in ET cells compared to PG and

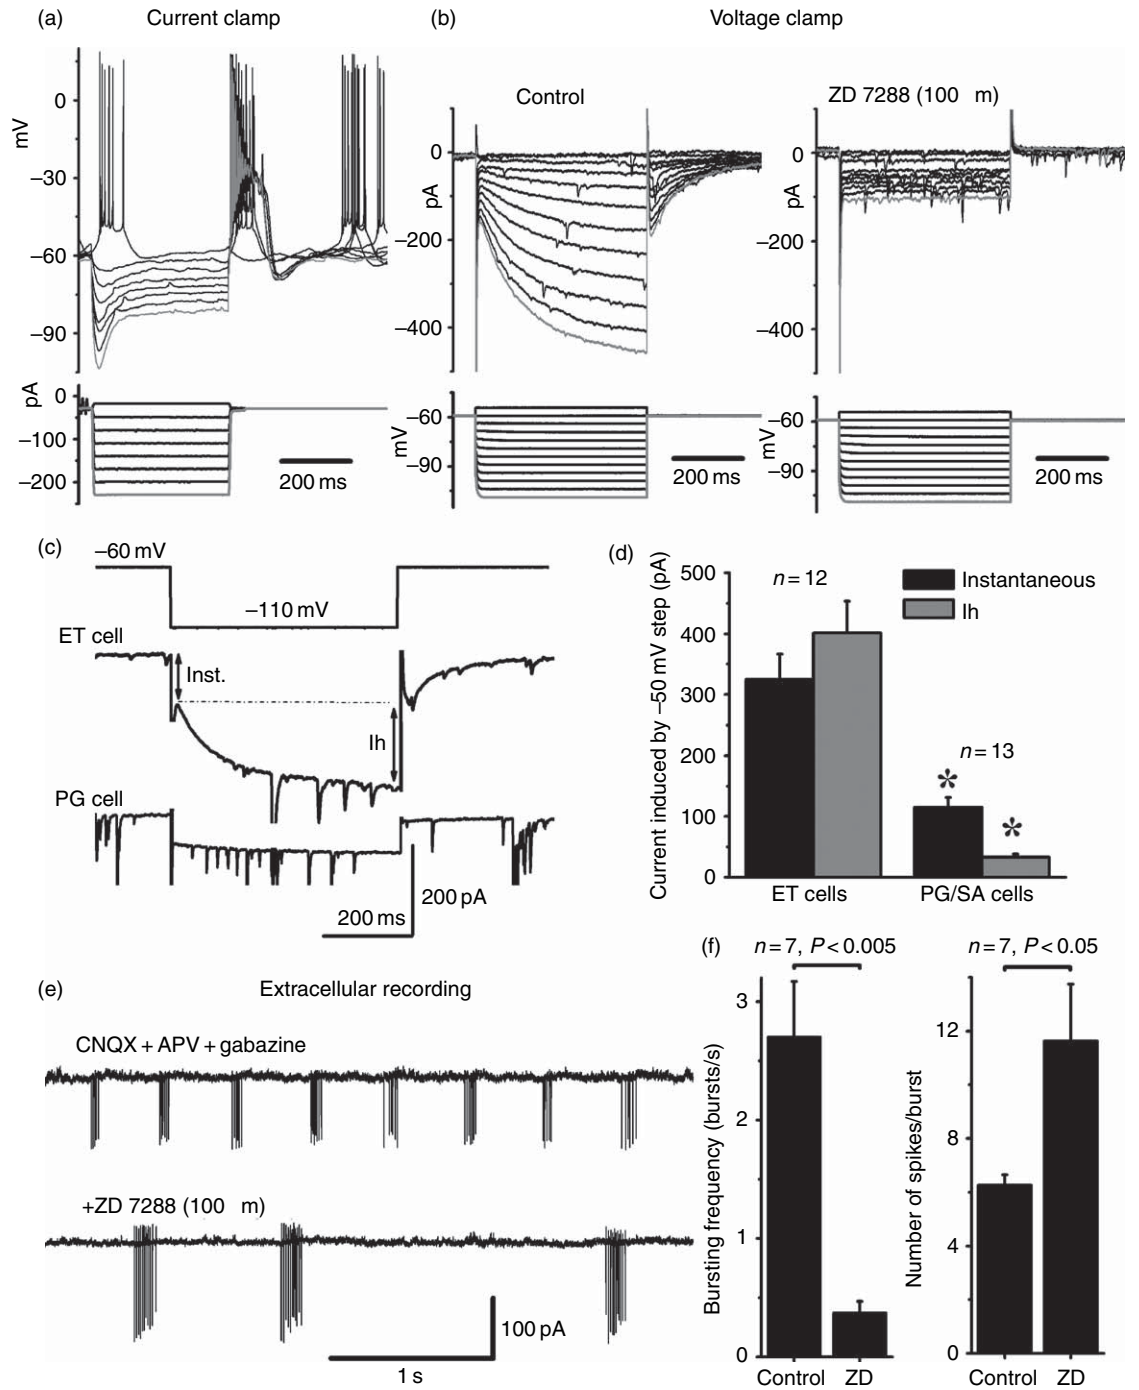

Figure 3 External tufted (ET) cells have a prominent Ih current. (a) Responses of an ET to hyperpolarizing and depolarizing current steps (bottom) in current clamp mode. Note the sag induced by membrane hyperpolarization, indicative of the presence of Ih current. After releasing the cell from the hyperpolarizing current, a rebound burst of spikes occurred. (b) Response of the same cell to membrane voltage steps (bottom) in voltage-clamp mode. A time-dependent inward current (Ih) was produced with hyperpolarizing voltage steps (<− 70 mV) followed by a rebound smaller inward current, which were blocked by the selective Ih current blocker, ZD 7288. (c) A periglomerular (PG) cell exhibits a much smaller Ih current (in response to a hyperpolarizing step from −60 to −110 mV, voltage-clamp mode) than an ET cell. (d) Group data show that ET cells have significantly larger Ih current than PG and short axon (SA) cells. The instantaneous current (Inst) reflects the membrane conductance which is larger in ET cells, indicating that PG/SA cells have on average a relative much higher input resistance. (e) The bursting frequency of an extracellularly recorded spontaneously bursting ET cell (in the presence of CNQX, AP5, and gabazine) decreased in response to application of the Ih blocker ZD 7288. However, the number of spikes/burst increased as shown in the grouped data in (f).

SA cells and that it contributes to tonic depolarization of ET cells because the specific Ih blocker, ZD 7288, significantly reduced the bursting frequency (Figure 3). Ih participates in burst timing and rhythmicity in other brain structures (DiFrancesco, D. 1993; Lüthi, A. and McCormick, D. A. 1998; Pape, H. C. 1996) and is modulated by Ca^{2+}. Thus, Ih and Ca^{2+} may play a role in burst termination and/or setting the interburst interval.

Rhythmic bursting, but not the LTS, was blocked by extracellular TTX and by intracellular dialysis with QX-314. These results suggest that, as for many neocortical neurons (Brumberg, J. C. *et al.*, 2000), burst generation in ET cells requires slowly inactivating Na^+ channels, that is, a persistent Na^+ current. Indeed, all ET cells tested had a prominent TTX-sensitive, persistent Na^+ current. The characteristics of this current are well suited to trigger spontaneous bursting in ET cells. The inward current activates near −60 mV, slightly hyperpolarized to the mean ET cell resting potential (−52 mV). Thus, it is reasonable to conjecture that as this persistent Na^+ current slowly depolarizes the ET cell membrane, additional Na^+ channels are activated further depolarizing the membrane to the threshold for action potential generation. This current maintains a level of depolarization sufficient to generate additional action potentials until another mechanism(s), possibly involving Ca^{2+} (see above), terminates the burst by transiently hyperpolarizing the membrane below the activation threshold for the persistent Na^+ current. As the membrane repolarizes, the persistent Na^+ current is re-engaged, and the burst cycle is repeated.

4.37.2.1.2 PG cells

These cells are the most numerous cells in the GL, and they are thought to be inhibitory in nature. They are small (5–8 μm), spherical or ovoid, and they are distributed in the PG regions surrounding the glomeruli (Figures 1 and 2). Their dendrites are typically restricted to a small subregion of a glomerulus (Pinching, A. J. and Powell, T. P., 1971a; Hayar, A. *et al.*, 2004a; 2004b). Their dendrites receive asymmetrical (morphologically excitatory) synapses from ET and mitral/tufted cell dendrites; only a relatively small subpopulation of PG cells receives synapses from ON terminals. Some of the mitral/tufted cell to PG cell synapses are paired with reciprocal symmetrical (morphologically inhibitory) synapses from PG cells back onto the parent mitral/tufted cell dendrites (Pinching, A. J. and Powell, T. P., 1971b; Toida, K. *et al.*, 1998; Kasowski, H. J. *et al.*, 1999; Toida, K. *et al.*, 2000). Physiological recordings indicate that PG cells also receive monosynaptic dendrodendritic excitatory input from ET cells (Hayar, A. *et al.*, 2004b). Axons of PG cells are rare but have been reported to extend over distances equivalent to four to five glomeruli (Blanes, T., 1898; Pinching, A. J. and Powell, T. P., 1971a; Hayar, A. *et al.*, 2004a). They appear to form symmetrical (morphologically inhibitory) synapses onto mitral/tufted cell dendrites and onto ET cells and other JG cells (Pinching, A. J. and Powell, T. P., 1971c). Most PG cells are GABAergic (Ribak, C. E. *et al.*, 1977; Mugnaini, E. *et al.*, 1984; Kosaka, T. *et al.*, 1985; 1987a; 1987b; 1987c; Kosaka, K. *et al.*, 1987; 1988). The GL also contains the largest population of dopamine (DA)-containing cells in the brain. The majority of DA-containing cells are PG cells, but some ET cells are also dopaminergic (Halász, N. *et al.*, 1977; Davis, B. J. and Macrides, F., 1983; Halász, N. *et al.*, 1985; Gall, C. *et al.*, 1986; McLean, J. H. and Shipley, M. T., 1988). About 80% of the DA cells contain GABA, which corresponds to about 50% of GABAergic cells (Kosaka, T. *et al.*, 1985; Gall, C. M. *et al.*, 1987; Kosaka, T. *et al.*, 1987b; Kosaka, K. *et al.*, 1987; 1988; 1995). Therefore, the DA PG neurons are regarded as a subpopulation of GABAergic neurons. Some PG cell subtypes also stain for thyrotropin-releasing hormone (TRH), enkephalin, nicotinamide adenine dinucleotide phosphate (NADPH)-diaphorase, neuropeptide-Y (NPY), somatostatin, and vasoactive intestinal polypeptide (VIP) (Bogan, N. *et al.*, 1982; Davis, B. J. *et al.*, 1982; Gall, C. *et al.*, 1986; Scott, J. W. *et al.*, 1987; Merchenthaler, I. *et al.*, 1988; Tsuruo, Y. *et al.*, 1988; Sanides-Kohlrausch, C. and Wahle, P., 1990a; Davis, B. J., 1991; Alonso, J. R. *et al.*, 1993; Kosaka, K. *et al.*, 1995; 1998; Kosaka, T. *et al.*, 1987c).

The spontaneous activity patterns of PG and SA cells differ markedly from ET cells. PG and SA cells *in vitro* have relatively low levels of spontaneous spike activity and lack the capacity to generate spike bursts in response to depolarizing currents (Figure 2) (Hayar, A. *et al.*, 2004a; 2004b). In slices, spikes in PG cells are driven primarily by spontaneous glutamatergic excitatory postsynaptic potentials (EPSPs). However, because of their heterogeneous neurochemical characteristics, PG cells are also likely to be functionally heterogeneous. For example, some studies have reported that different PG cell subtypes appear to exhibit different K^+

conductances (Puopolo, M. and Belluzzi, O. 1998) as well as different firing behaviors (McQuiston, A. R. and Katz, L. C., 2001). An estimated 10% of PG neurons in adulthood are positive for tyrosine hydroxylase (TH) (McLean, J. H. and Shipley, M. T., 1988; Kratskin, I. and Belluzzi, O., 2003), the rate-limiting enzyme for DA synthesis. Dopaminergic neurons have been recently identified *in vitro* using a transgenic mouse strain harboring an eGFP (enhanced green fluorescent protein) reporter construct under the promoter of TH. The most prominent feature of these cells when recorded in acutely dissociated cell culture preparations was the presence of regular spontaneous spiking at ~8 Hz. In these cells, five main voltage-dependent conductances were identified (Pignatelli, A. *et al.*, 2005): the two having largest amplitude were a fast transient Na^+ current and a delayed rectifier K^+ current. In addition, they have three smaller inward currents, sustained by Na^+ ions (persistent type) and by Ca^{2+} ions (low-voltage-activated (LVA) and high-voltage-activated (HVA)). The pacemaking activity was shown to be supported by the interplay of the persistent Na^+ current and of a T-type Ca^{2+} current. Transgenic mice in which catecholaminergic neurons expressed human placental alkaline phosphatase (PLAP) on the outer surface of the plasma membrane were also used to identify dissociated dopaminergic PG neurons (Puopolo, M. *et al.*, 2005). Dopaminergic PG cells spontaneously generated action potentials in a rhythmic fashion with an average frequency of 8 Hz. It was found that substantial Ca^{2+} current and TTX-sensitive Na^+ current flow during the interspike depolarization. These results show that dopaminergic PG cells have intrinsic pacemaking activity, supporting the possibility that they can maintain a tonic release of DA to modulate the sensitivity of the olfactory system during odor detection.

4.37.2.1.3 SA cells

These cells are roughly the same size (8–12 μm) as ET cells. They are distinguished by multiple dendrites that seem to harvest information from multiple glomeruli (Figures 1 and 2) (Hayar, A. *et al.*, 2004b). The dendrites may receive synaptic inputs from ET and mitral/tufted cell dendrites (Hayar, A. *et al.*, 2004b), tufted cell axon collaterals, or other SA cells. SA cells have axons that can extend up to 1–2 mm within the GL (Aungst, J. L. *et al.*, 2003). The axons appear to synapse primarily onto the dendrites of PG cells (Pinching, A. J. and Powell, T. P., 1971a). They do not receive direct ON input (Pinching, A. J. and Powell, T. P., 1971c; Hayar, A. *et al.*, 2004b). Their resting spontaneous activity patterns in MOB slices appear to be very similar to that of PG cells (Hayar, A. *et al.*, 2004b).

4.37.2.2 Electrophysiology of Intraglomerular Circuitry

4.37.2.2.1 Excitatory systems in the GL

4.37.2.2.1.(i) ON glutamatergic synaptic input to JG and mitral/tufted cells All studies to date have identified glutamate as the major transmitter at ON synapses onto the dendrites of JG neurons, as well as those of mitral/tufted cells in the GL. Release of glutamate from ON terminals is controlled by N- and P/Q-type Ca^{2+} channels (Isaacson, J. S. and Strowbridge, B. W., 1998; Murphy, G. J. *et al.*, 2004). Each glomerulus contains the apical dendritic tufts of about 20 mitral cells, 200 tufted cells, and 1500–2000 JG cells (reviewed in Ennis, M. *et al.*, 2007). A variety of studies demonstrated that sensory transmission from ON axon terminals to these dendrites is mediated by glutamate acting primarily at alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl D-aspartate (NMDA) ionotropic glutamate receptor subtypes (Bardoni, R. *et al.*, 1996; Ennis, M. *et al.*, 1996; Aroniadou-Anderjaska, V. *et al.*, 1997; Chen, W. R. and Shepherd, G. M., 1997; Keller, A. *et al.*, 1998; Aroniadou-Anderjaska, V. *et al.*, 1999a; Ennis, M. *et al.*, 2001). Thus, JG and mitral/tufted cell responses to ON input are excitatory (Figures 4 and 5). In addition, metabotropic glutamate receptors (mGluRs) are expressed by nearly all MOB neurons (see Ennis, M. *et al.*, 2007 for review). Comparatively less is known about the role of mGluRs at ON synapses. Electrophysiological and Ca^{2+}-imaging studies have reported that ON stimulation evokes an mGluR1-sensitive synaptic component in ~40% of mitral cells in normal physiological conditions in the slice (De Saint Jan, D. and Westbrook, G. L., 2005; Ennis, M. *et al.*, 2006; Yuan, Q. and Knopfel, T., 2006). In the presence of ionotropic glutamate receptor antagonists, ON-evoked, mGluR1-mediated synaptic responses were markedly enhanced by inhibition of glutamate transporters (e.g., TBOA) (Figure 5). Thus, activation of mGluR1 is tightly regulated by glutamate uptake mechanisms. mGluR1-mediated responses were maximal with bursts of 50–100 Hz ON spikes, similar to frequencies of odor-induced spikes in ORNs *in vivo* (Duchamp-Viret, P. *et al.* 1999). Activation of mGluRs has also been suggested

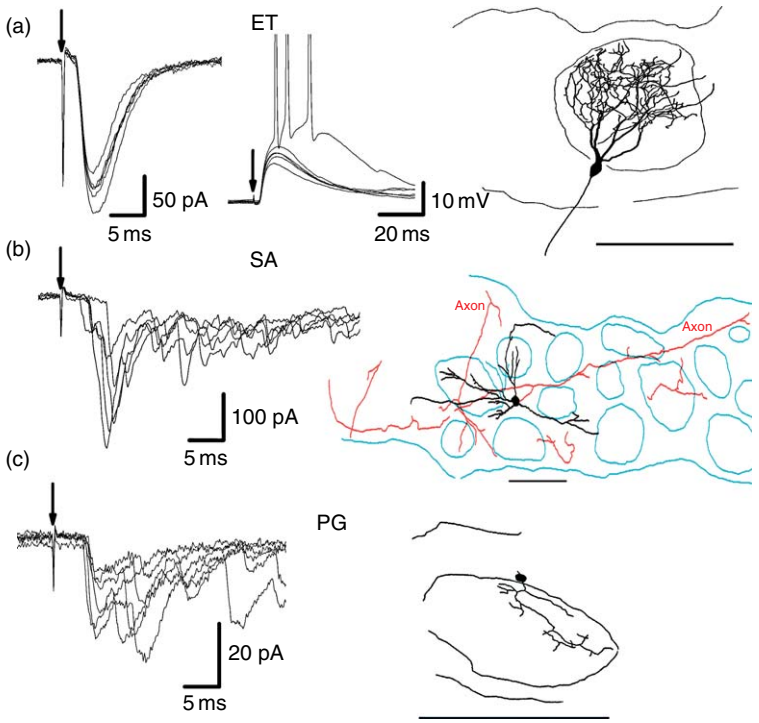

Figure 4 Olfactory nerve (ON)-evoked synaptic responses in juxtaglomerular (JG) cell subtypes. Panels a–c show six superimposed voltage-clamp traces (holding potential = −60 mV in this and subsequent panels) of ON-evoked EPSCs in external tufted (ET), short axon (SA), and periglomerular (PG) cells, respectively. Arrows indicate time of stimulation. Cell morphology is shown at right. Scale bars, 100 μm. ON stimulation produced short, constant latency EPSCs in the ET cell (a, left panel), indicative of monosynaptic input. In current clamp, ON stimulation evoked a constant, short latency EPSPs of variable amplitude (a, middle panel). The largest EPSPs triggered the generation of a burst of action potentials (truncated for clarity). Panels b and c show that ON stimulation evoked longer, variable latency EPSCs bursts in SA (b) and PG (c) cells, indicative of di- or polysynaptic responses. Adapted from Hayar, A. *et al.*, 2004, J. Neurosci. 24, 6676–6685., with permission from The Society for Neuroscience.

to produce long-term depression at ON to mitral cell synapses (Mutoh, H. *et al.*, 2005).

All ET cells receive monosynaptic ON input, which appears to be primarily mediated by AMPA and NMDA receptors in normal physiological conditions *in vitro* (Figure 4) (Hayar, A. *et al.*, 2004a; 2004b; 2005). If the amplitude of an ON-evoked EPSP reaches threshold for spike generation, a spike burst is always triggered in ET cells (Hayar, A. *et al*, 2004a). Further increases in ON stimulation strength produce the same all-or-none burst. Thus, ET cells receive monosynaptic ON input that is converted into an all-or-none spike burst. Accordingly, ET cells amplify suprathreshold sensory input at the first stage of synaptic transfer in the olfactory system. ET cells also readily entrain to rhythmic ON input delivered at theta frequencies (5–10 Hz) characteristic of investigative sniffing in rodents. As noted above, the intrinsic spontaneous bursting rate of ET cells ranges from 1 to 8 bursts/s. This might suggest that ET cells with different spontaneous bursting rates may be preferentially entrained by repetitive sensory input at or near their intrinsic bursting frequency. This turns out not to be the case as ET cells, irrespective of their intrinsic spontaneous bursting frequencies, can be entrained by repetitive, 5–10 Hz ON input (Hayar, A. *et al.*, 2004a).

The majority of PG cells exhibit longer latency, prolonged bursts of EPSP/Cs in response to ON stimulation than ET cells (Figure 4). The long, variable latency of these responses is indicative of di- or polysynaptic ON input. Thus, most SA and PG cells do not appear to receive direct ON input, perhaps because their dendrites ramify in glomerular compartments devoid of ON terminals. Only 20% of PG cells had short, relatively constant latency EPSCs following ON stimulation, and in some of these cells, the short latency synaptic response was followed by a delayed burst of EPSP/Cs. SA cells also

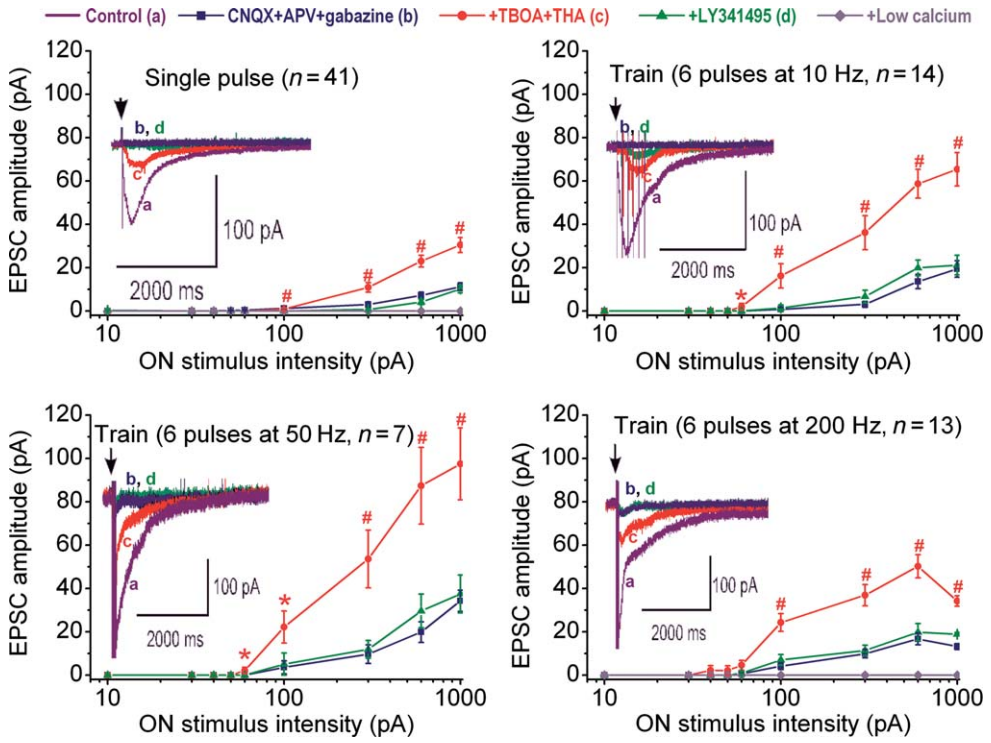

Figure 5 Olfactory nerve (ON)-evoked EPSCs elicited in the presence of glutamate uptake inhibitors (TBOA and THA) are dependent on stimulation intensity and frequency. The four panels show plots of the peak amplitude of ON-evoked EPSCs as a function of ON stimulation intensity (10–1000 μA); each panel shows data for a different ON stimulation frequency. Insets in each graph show traces of ON-evoked EPSCs in different pharmacological conditions; traces are averages of five ON-evoked EPSCs. Colored lines correspond to the pharmacological conditions indicated at the top; note that control data are not plotted on the line graphs. TBOA–THA significantly increases the ON-evoked EPSCs at a threshold intensity of 60–100 μA for all frequencies. Residual responses remaining in the presence of LY341495 and CNQX, APV, and gabazine were abolished by low Ca^{2+}-ACSF, as shown for the single-pulse and 200 Hz stimulation frequencies. $^{*}P < 0.05$, $\#P < 0.001$ vs. CNQX, APV, and gabazine. Adapted from Ennis, M., Zhu, M., Heinbockel, T., and Hayar, A. 2006. Olfactory nerve-evoked metabotropic glutamate receptor-mediated responses in olfactory bulb mitral cells. J. Neurophysiol. 95, 2233–2241, with permission from The American Physiological Society.

responded to ON stimulation with long, variable latency, prolonged bursts of EPSP/Cs and never exhibited responses consistent with monosynaptic ON input (Figure 4). These findings indicate that (1) SA cells and most PG cells lack direct ON input and (2) ET cells along with mitral/tufted cells are the major postsynaptic targets of ON inputs.

Since most (~80%) PG cells, and all SA cells, lack monosynaptic ON input, this suggests that most PG cells are functionally associated with glomerular compartments lacking ON terminals. Anatomical studies have revealed that the glomeruli have a bicompartmental organization. Each glomerulus has several interdigitating compartments, one of which is rich in ON terminals and the second of which is devoid of ON input (Kosaka, K. *et al.*, 1997; Kasowski, H. J. *et al.*, 1999). Calbindin-positive JG neurons extend their dendrites only into glomerular compartments devoid of ON terminals, suggesting that they do not receive direct sensory innervation (Toida, K. *et al.*, 1998; 2000). It is reasonable to speculate, therefore, that the SA and PG cells that do not receive direct input (Hayar, A. *et al.*, 2004b) may correspond to these calbindin-positive JG neurons. These PG cells might provide localized inhibition to mitral/tufted cell dendrites, or other nearby JG cells. Dopaminergic and GABAergic PG cells presynaptically inhibit ON terminals (Hsia, A. Y. *et al.*, 1999; Wachowiak, M. and Cohen, L. B., 1999; Aroniadou-Anderjaska, V. *et al.*, 2000; Berkowicz, D. A. and Trombley, P. Q., 2000; Ennis, M. *et al.*, 2001; Murphy, G. J. *et al.*, 2005; Wachowiak, M. *et al.*, 2005). Since at least 20% of PG cells receive monosynaptic ON input, it is possible that these cells primarily mediate this presynaptic inhibition of the ON. In contrast

to PG cells, SA cells extend dendrites and axons across multiple glomeruli and are thought to be involved in interglomerular functions, such as center-surround inhibition of neighboring glomeruli (Aungst, J. L. *et al.*, 2003).

4.37.2.2.1.(ii) Spillover of dendritically released glutamate As noted above, the apical dendrites of ET and mitral/tufted cells that ramify in the glomeruli release glutamate. Although the dendrites of these cell types do not form synapses with each other, the release of glutamate from the apical dendrites has been reported to produce nonsynaptically mediated excitation (i.e., glutamate spillover) of the parent cell releasing glutamate (self- or autoexcitation) or neighboring cells (Figure 6). Such excitation is facilitated by removal of Mg^{2+} from the extracellular media, which enhances the activation of NMDA receptors. Alternatively, spillover-mediated excitatory responses can be facilitated in the presence of physiological levels of extracellular Mg^{2+} by blockade of $GABA_A$ receptors (Salin, P. A. *et al.*, 2001; Friedman, D. and Strowbridge, B. W., 2000). Under such conditions, intracellular depolarization of individual mitral cells produces long-duration, NMDA receptor-dependent excitation of the same cell or adjacent mitral cells (Aroniadou-Anderjaska, V. *et al.*, 1999b; Isaacson, J. S., 1999; Friedman, D. and Strowbridge, B. W., 2000; Salin, P. A. *et al.*, 2001; Christie, J. M. and Westbrook, G. L., 2006). ET cells have also been reported to exhibit such self-excitation (Murphy, G. J. *et al.*, 2005). The mitral cell self-excitation can be blocked by intracellular Ca^{2+} chelation or blockade of voltage-gated Ca^{2+} channels (Friedman, D. and Strowbridge, B. W., 2000; Salin, P. A. *et al.*, 2001). The self-excitation responses are graded and increase with the number of spikes or depolarizing pulses applied to the mitral cell (Friedman, D. and Strowbridge, B. W., 2000; Salin, P. A. *et al.*, 2001). It has been suggested that the NMDA autoreceptors may serve to increase the firing frequency of mitral cells during prolonged discharges (Friedman, D. and Strowbridge, B. W., 2000). Such excitation can also be evoked by antidromic activation of mitral cells (Figure 6) (Chen, W. R. and Shepherd, G. M., 1997; Aroniadou-Anderjaska, V. *et al.*, 1999b). This glutamate spillover-mediated, NMDA receptor-dependent excitation appears to occur chiefly among the lateral dendrites of mitral cells, while an AMPA receptor-dependent spillover occurs among the apical dendrites of mitral/tufted cells (Aroniadou-Anderjaska, V. *et al.*, 1999b; Salin, P. A. *et al.*, 2001; Schoppa, N. E. and Westbrook, G. L., 2001; 2002; Christie, J. M. and Westbrook, G. L., 2006). Electrotonic coupling among mitral cell dendrites in the same glomerulus facilitates spillover responses mediated by AMPA receptors (Schoppa, N. E. and Westbrook, G. L., 2002; Christie, J. M., and Westbrook, G. L., 2006).

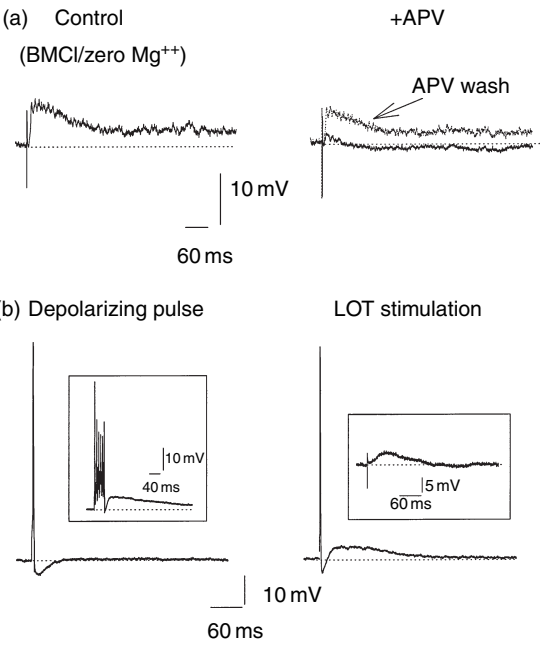

Figure 6 Mitral cells generate an NMDA receptor-dependent EPSP in response to antidromic stimulation of neighboring mitral/tufted cells. Panels a and b show recordings from two different cells in Mg^{2+}-free medium and bicuculline (10 μM). (a) Antidromic activation of mitral/tufted cells by lateral olfactory tract (LOT) stimulation, subthreshold for the recorded neuron, evoked an EPSP that was reversibly blocked by bath-applied APV (50 μM). (b) Mitral cell shown did not produce a prolonged depolarization in response to a 5 ms intracellular current pulse. However, a prolonged depolarization was evoked by longer current pulses (40 ms, shown in inset) or LOT stimulation with or without (inset) an antidromic spike. Traces are averages of five to ten sweeps. Reprinted from V. Aroniadou-Anderjaska, V., Ennis, M., and Shipley, M. T. 1999b. Dendrodendritic recurrent excitation in mitral cells of the rat olfactory bulb. J. Neurophysiol. 82, 489–494, with permission from The American Physiological Society.

Other glomerulus-specific glutamate-mediated excitatory interactions among mitral cells have been reported. Reciprocal glutamate-mediated excitation was reported between closely adjacent mitral cells whose apical dendrites extended into the same glomerulus (Urban, N. N. and Sakmann, B., 2002). The latency for the mitral to mitral cell EPSPs was surprisingly short, in line with monosynaptic mediation,

despite the fact that mitral cells do not form anatomical synapses with each other. The EPSP was primarily mediated by AMPA receptors and originated within the GL, suggesting that they are generated in the apical dendrites of mitral cells. In contrast to the preceding studies, Carlson G. C. *et al.* (2000) reported that ON stimulation and antidromic activation of multiple mitral/tufted cells, but never activation of single mitral cells, elicited long-lasting depolarizations (LLDs) in mitral cells. The LLDs were all-or-none in nature, required activation of AMPA receptors, and originated in the glomeruli. Further, spontaneous LLDs were synchronous among mitral cells associated with the same, but not different glomeruli. The LLDs appear to be a network phenomenon, presumably reflecting recurrent, intraglomerular glutamate release from an ensemble of mitral/tufted cell apical dendrites. Recently, Karnup S. V. *et al.* (2006) described field potentials that are generated spontaneously in the GL in olfactory bulb slices (Figure 7). These spontaneous glomerular local field potentials (sGLFPs) had variable shape and amplitude and occurred at irregular intervals. They are similar to LLDs in mitral cells (Carlson, G. C. *et al.*, 2000) in that they are mediated mostly by AMPA/kainate receptors and are enhanced during blockade of $GABA_A$ receptors. They persisted after the removal of the MCL, indicating that they are predominantly generated from by GL neurons. Nevertheless, they were correlated with mitral cell postsynaptic LLDs, suggesting the existence of a common generator (Figure 7). The observation that sGLFPs precede LLDs in mitral cells suggests that mitral cells are followers rather than initiators of population events. The most likely scenario is that mitral cells are activated when a critical number of glutamate-releasing JG neurons (presumably ET cells) are activated. Such a triggering mechanism may be produced by synchronous spike bursts in ET cells of the same glomerulus (Hayar, A. *et al.*, 2004a; 2004b). The role of spillover-mediated excitation among mitral/tufted cells is discussed below in Synchrony.

4.37.2.2.1.(iii) ET and mitral/tufted cell dendrodendritic input to PG and SA cells ET and mitral/tufted cells form glutamatergic dendrodendritic synapses with PG and SA cells. This topic is

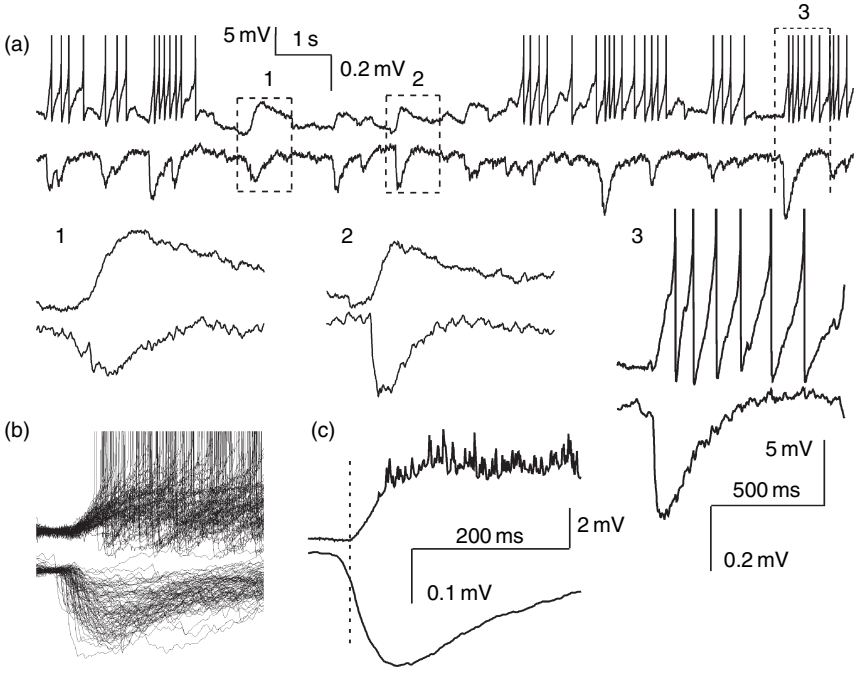

Figure 7 Glomerular and mitral cell long-lasting depolarizations (LLDs). Simultaneous recordings of spontaneous LLDs (sLLDs) in a mitral cell and spontaneous glomerular layer field potentials (sGLFPs) from the glomerulus containing the mitral cell tuft. (a) Dual sweep of intracellular (upper trace) and field activity (lower trace). Spikes of the mitral cell are truncated. Insets with an expanded timescale demonstrate variability of sGLFP locked to sLLD and different kinetics of sGLFP as compared with sLLD. (b) Overlapping sweeps with sLLD/sGLFP pairs ($n = 80$). Note 10-fold difference between smallest and biggest sGLFP indicating different amount of cells involved in successive sGLFP in a given glomerulus. (c) Averaged sLLD and sGLFP ($n = 80$) with the reference point set at the sLLD onset show 9.8 ms delay of sLLD upon initiation of sGLFP.

discussed below in *ET and mitral/tufted cell dendrodendritic interactions with PG and SA cells*.

4.37.2.2.2 Inhibitory systems in the GL

4.37.2.2.2.(i) Presynaptic inhibition of ON terminals

4.37.2.2.2.(i).(a) DA and D2 receptors The GL contains several hundred thousand DA neurons – PG neurons – but the MOB receives no known extrinsic DA input. In mammals, D1 receptor mRNA is expressed in the GL and GCL (Coronas, V. *et al.*, 1997), while immunocytochemical localization of D1 receptors is faint and primarily in the GCL (Levey, A. I. *et al.*, 1993). By contrast, D1-like binding is present at very low levels in all layers of the MOB with the exception of the ONL (Mansour, A. *et al.*, 1990; Nickell, W. T. *et al.*, 1991; Coronas, V. *et al.*, 1997). The functional significance of D1 receptors in MOB remains unclear. By contrast, only the ONL and GL have high densities of D2 receptors in rats and mice (Mansour, A. *et al.*, 1990; Nickell, W. T. *et al.*, 1991; Levey, A. I. *et al.*, 1993; Coronas, V. *et al.*, 1997; Koster, N. L. *et al.*, 1999) and to a lesser extent in guinea pigs, but not in cats or monkeys (Camps, M. *et al.*, 1990). In the GL, the JG neurons express D2 receptors (Mansour, A. *et al.*, 1990). Some immunocytochemical labeling for D2 receptors, as well as *in situ* hybridization, has been reported in the GCL and EPL; however D2-binding sites are consistently restricted to the ONL and GL (Mansour, A. *et al.*, 1990; Levey, A. I. *et al.*, 1993; Coronas, V. *et al.*, 1997). Other anatomical evidence indicates that most, if not all, of the D2 receptors in the GL occur on ON axon terminals. ORNs express D2 receptors and bulbectomy, a manipulation that causes retrograde degeneration of ORNs, eliminates D2 receptor mRNA in the olfactory epithelium (Koster, N. L. *et al.*, 1999). Taken together, these findings indicate that DA released from JG neurons may presynaptically modulate ON terminals via activation of D2 receptors.

In agreement with this, DA and D2 receptor agonists reduced spontaneous and ON-evoked activity in mitral and JC cells (Figure 8), as well as odor-evoked activity in the GL and odor detection performance, in a variety of species (Nowycky, M. C. *et al.*, 1983; Doty, R. L. and Risser, J. M., 1989; Sallaz, M. and Jourdan, F., 1992; Hsia, A. Y. *et al.*, 1999; Wachowiak, M. and Cohen, L. B., 1999; Berkowicz, D. A. and Trombley, P. Q., 2000; Ennis, M. *et al.*, 2001). These effects are mediated by presynaptic suppression of glutamate release from ON terminals via inhibition of Ca^{2+} influx (Wachowiak, M. and Cohen, L. B., 1999). In a similar manner, DA and D2 receptor agonists suppressed spontaneous and ON-evoked activity in JG cells but had no effect on mitral to JG cell transmission (Ennis, M. *et al.*, 2001). The inhibitory effects of DA were abolished in D2 receptor-knockout mice (Ennis, M. *et al.*, 2001). Presynaptic inhibition of ON terminals by DA (and GABA, see below) provides a mechanism for increasing the range of concentrations that can be processed by MOB neurons: as activity increases in ON terminals, DA JG cells are more strongly excited. This, in turn, provides negative feedback onto ON terminals, reducing the release of glutamate. Such a scheme would effectively increase the dynamic range of information transfer from ORNs to MOB neurons. Interestingly, systemic administration of D2 receptor agonists has been reported to prevent odorant-specific 2-dexyglucose patterns in MOB and to reduce odorant detectability (Doty, R. L. and Risser, J. M., 1989; Sallaz, M. and Jourdan, F., 1992). Related to this question of how DA participates in odor processing is the degree to which these receptors are tonically active *in vivo*? If, for example, ON terminals are tonically inhibited by DA via D2 receptors, this might serve to filter out weak signals (noise). This might sharpen the spatial pattern of active glomeruli and facilitate detection of predominant odors. There is experimental support for this possibility. Blockade of D2-like receptors by systemic administration of spiperone increased the number of mitral cells that responded to single or multiple odorants (Wilson, D. A. and Sullivan, R. M., 1995). One interpretation of this study is that reduced D2 presynaptic inhibition of ON terminals increases the odor responsiveness of mitral cells but does so at the cost of reduced odorant discrimination.

4.37.2.2.2.(i).(b) GABA and $GABA_B$ receptors $GABA_B$ receptors play a presynaptic inhibitory role similar to that just described for D2 receptors. As noted above, GABAergic PG cells represent a large population of GL interneurons. In the rat MOB, the glomeruli have the highest concentration of $GABA_B$ receptors as determined by radioligand binding (Bowery, N. G. *et al.*, 1987; Chu, D. C. M. *et al.*, 1990) and by immunohistochemical localization of $GABA_B$ receptor subunits (Margeta-Mitrovic, M. *et al.*, 1999). EM immunohistochemistry revealed that the dense labeling in the GL is due to the presence of $GABA_B$ receptors on ON terminals and on the somata of PG cells (Bonino, M. *et al.*, 1999). A variety of imaging

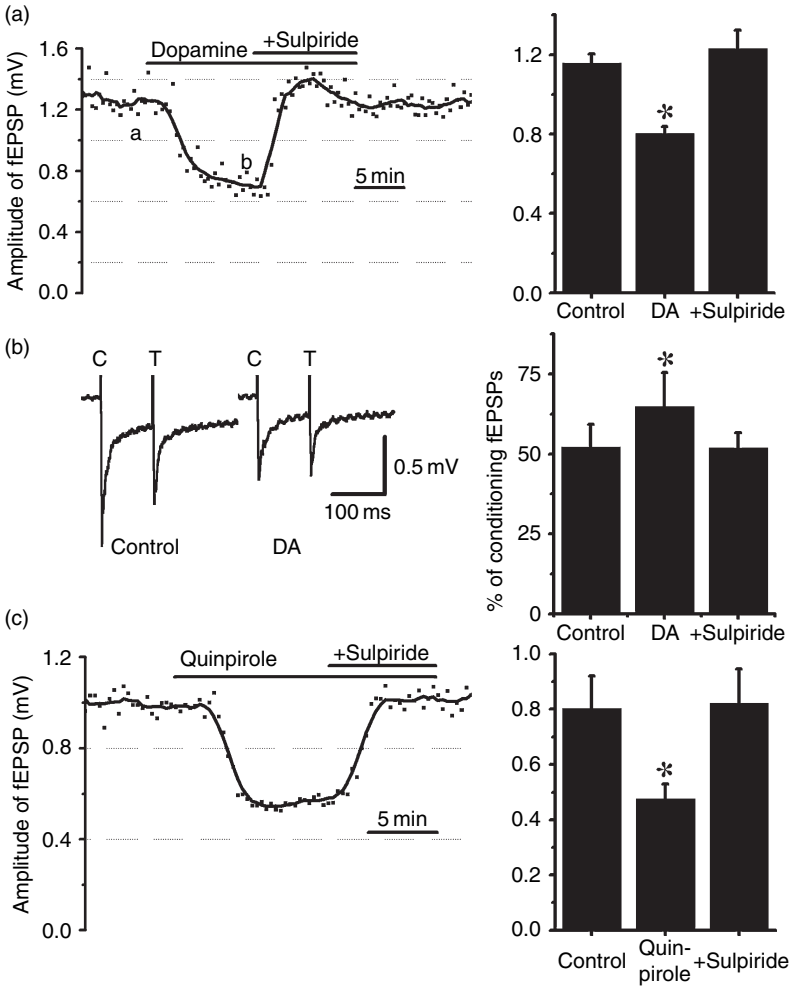

Figure 8 Dopamine (DA) suppresses the olfactory nerve (ON)-evoked field excitatory postsynaptic potential (fEPSP) recorded in the rat glomerular layer (GL). (a) Line graph from a typical experiment showing the suppression of the GL fEPSP by bath application of DA (40 μM). Values represent the peak amplitude ± SE of the fEPSP. DA-induced suppression (30.7%) was fully reversed by the D2 antagonist sulpiride (100 μM). Group data at the right from similar experiments show that DA significantly suppresses ($n = 5$, $^*P = 0.005$) the ON-evoked fEPSP, an effect fully reversed by sulpiride ($n = 4$). (b) Records show responses to paired-pulse stimulation of the ON (100-ms interstimulus intervals) before (Control) and during application of DA (DA); control and DA records correspond to time points a and b indicated in panel a. In control artificial cerebrospinal fluid (ACSF), paired ON shocks produced pronounced paired-pulse depression of the test fEPSP. DA preferentially suppressed the conditioning shock fEPSP and decreased paired-pulse depression. Traces are averages of five sweeps. Bar graph of group data showing the change in paired-pulse responses to ON stimulation; data are expressed as the amplitude of the test fEPSP as a percentage of the conditioning fEPSP. Note that DA significantly reduced paired-pulse depression ($n = 4$, $^*P = 0.01$). (c) Line graph showing the suppression of the GL fEPSP by bath application of quinpirole (100 μM). Sulpiride (100 μM) fully reversed the quinpirole-induced suppression. Group data for similar experiments are shown in the bar graphs to the right ($n = 10$, $^*P < 0.0001$). Reprinted from Ennis, M., Zhou, F. M., Ciombor, K. J., Aroniadou-Anderjaska, V., Hayar, A., Borrelli, E., Zimmer, L. A., Margolis, F., and Shipley, M. T. 2001. Dopamine D2 receptor-mediated presynaptic inhibition of olfactory nerve terminals. J. Neurophysiol. 86, 2986–2997, with permission from The American Physiological Society.

and electrophysiological studies have provided solid evidence that GABA released from PG neurons presynaptically inhibits glutamate release from ON terminals via activation of these $GABA_B$ receptors (Figure 9) (Keller, A. *et al.*, 1998; Wachowiak, M. and Cohen, L. B., 1999; Aroniadou-Anderjaska, V. *et al.*, 2000; Palouzier-Paulignan, B. *et al.*, 2002; Murphy, G. J. *et al.*, 2005). The presynaptic inhibition of glutamate release is mediated by the suppression of Ca^{2+} influx into ON terminals (Wachowiak, M. *et al.*,

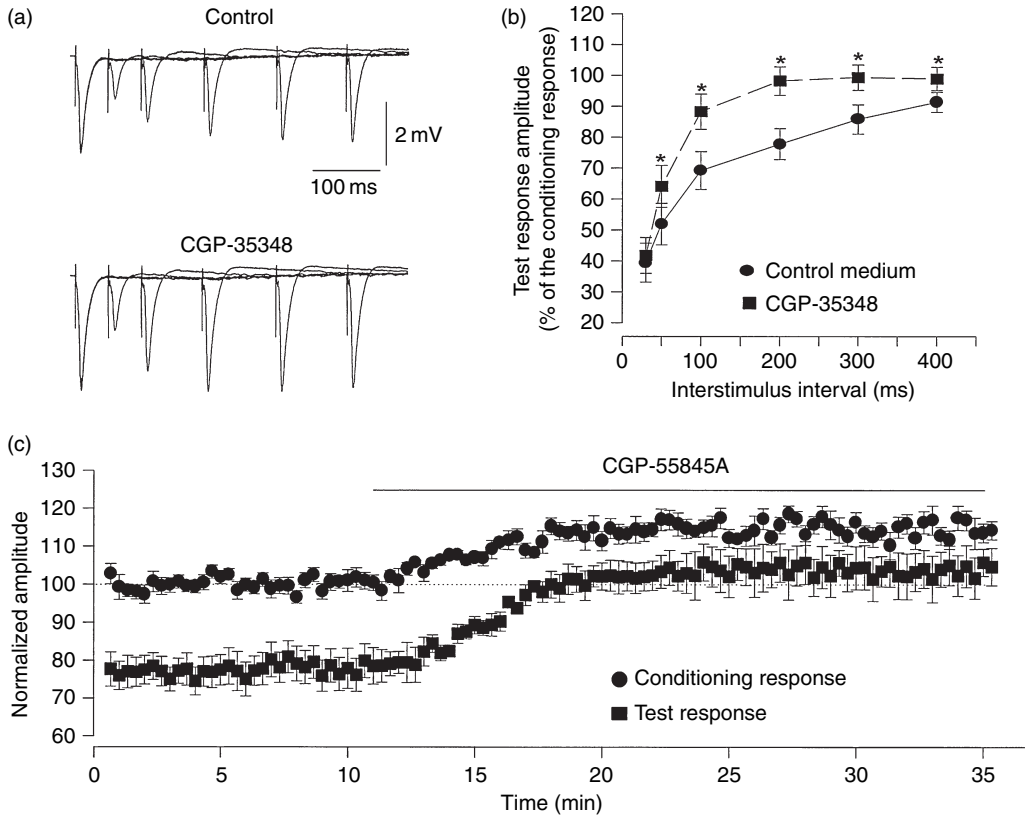

Figure 9 $GABA_B$ receptors on olfactory nerve (ON)terminals are activated both tonically and in response to ON stimulation. $GABA_B$ antagonists increase both conditioning and test responses of mitral/tufted cells to paired-pulse stimulation of the ON, while reducing paired-pulse depression (PPD) of test responses. In all experiments, AP5 is included in the medium. (a) Responses to paired-pulse stimulation of the ON (interstimulus intervals 50, 100, 200, 300, and 400 ms) before and after application of the $GABA_B$ antagonist CGP-35348 (1 mM). The $GABA_B$ antagonist increased the amplitude of the conditioning response and reduced or blocked PPD. Each trace is an average of five sweeps, and five traces are superimposed. (b) Group data ($n = 10$) of the effects of CGP-35348 (500 μM to 1 mM) on PPD of the ON-evoked glomerular field EPSP. The reduction of PPD was statistically significant ($^*P < 0.05$) at interstimulus intervals from 50 to 400 ms. (c) Time course of the effects of CGP-55845A (10 μM) on conditioning and test responses (interstimulus interval 100 ms). Group data from six slices. Reprinted from Aroniadou-Anderjaska, V., Zhou, F. M., Priest, C. A., Ennis, M., and Shipley, M. T. 2000. Tonic and synaptically evoked presynaptic inhibition of sensory input to the rat olfactory bulb via GABA(B) heteroreceptors. J. Neurophysiol. 84, 1194–1203, with permission from The American Physiological Society.

2005). Stimulation of individual PG cells has been reported to inhibit, via $GABA_B$ receptors, ON input onto the stimulated cell (Murphy, G. J. *et al.*, 2005). The MOB also contains the highest levels of the putative inhibitory transmitter taurine, exceeding concentrations of GABA and glutamate (Collins, G. G., 1974; Margolis, F. L., 1974; Banay-Schwartz, M. *et al.*, 1989a; 1989b; Ross, C. D. *et al.*, 1995; Kamisaki, Y. *et al.*, 1996). Taurine is found in ON axons, in various neurons, and in astrocytes (Kratskin, I. L. *et al.*, 2000; Kratskin, I. and Belluzzi, O., 2002; Pow, D. V. *et al.*, 2002). In the ON terminals and some postsynaptic dendrites, taurine is colocalized with glutamate (Didier, A. *et al.*, 1994). Observation of spontaneous taurine release from MOB synaptosomes suggests that taurine may be abundantly released (Kamisaki, Y. *et al.*, 1996). In electrophysiological recordings, taurine directly activated presynaptic $GABA_B$ receptors and inhibited ON terminals, and it also induced Cl^- currents in mitral/tufted cells. Surprisingly, taurine had no direct effect on PG cells (Belluzzi, O. *et al.*, 2004).

4.37.2.2.2.(i).(c) ET and mitral/tufted cell dendrodendritic interactions with PG and SA cells As noted above, ET and mitral/tufted cells form excitatory glutamatergic dendrodendritic synapses with PG and SA cells in the glomeruli. PG cells, and

perhaps SA cells, in turn, form inhibitory GABAergic dendrodendritic synapses with ET and mitral/tufted cells. Although the ET and mitral/tufted cell input is excitatory, this topic is considered here for simplicity. Compared to the dendrodendritic synapses between mitral/tufted and GCs in the EPL, far less is known about the properties of the dendrodendritic synapses in the GL. PG and SA cells were reported to receive spontaneous bursts of glutamatergic EPSCs (Hayar, A. *et al.*, 2004b). Since SA cells and most PG cells do not receive direct ON input, this input must arise from other excitatory elements within the glomeruli. Prime candidates include the apical dendrites of ET cells and mitral tufted cells. Consistent with this, stimulation of the MCL or lateral olfactory tract (LOT) has been used to produce antidromic spikes which propagate into, and trigger glutamate release from, mitral/tufted cell apical dendrites. Such stimulation was reported to excite JG cells in the GL (Ennis, M. *et al.*, 2001). More recently, spontaneous spike bursts or direct depolarization of individual ET cells to elicit spike bursts were reported to trigger EPSC bursts in PG and SA cells mediated by activation of AMPA receptors (Figure 10) (Hayar, A. *et al.*, 2004b). The latency of the evoked EPSCs (0.85 ms) was indicative of monosynaptic input to PG cells from ET cells. Additional studies demonstrated that this ET cell to PG/SA cell excitatory transmission is intraglomerular as it was only observed between cells associated with the same glomerulus. Stimulation of an individual ET cell was reported to produce large EPSCs and Ca^{2+} spikes in PG cells (Murphy, G. J. *et al.*, 2005). The NMDA receptor antagonist 2-amino-5-phosphono-valeric acid (APV) had minimal effects on the EPSP but abolished the Ca^{2+} spike. The same study reported that stimulation of a single ET cell excites two to seven unidentified JG cells within the same glomerulus, suggesting that individual ET cells synapse with multiple PG cells.

Single spikes in ET cells are relatively ineffective in triggering GABA release from PG cells (Murphy, G. J. *et al.*, 2005). Multiple spikes, leading to LVA Ca^{2+} currents, are much more effective in releasing GABA from PG cells (Murphy, G. J. *et al.*, 2005). These findings suggest that GABA release from PG cells may be preferentially triggered when these cells receive strong synaptic input. ET cells, individually and collectively, provide strong input to PG cells. Spike bursts in individual ET cells robustly activate PG cells. Additionally, individual ET cells appear to activate, on average, five PG cells (Murphy, G. J. *et al.*, 2005). Since ET cells spontaneously generate synchronous spike bursts and provide convergent input to a multiple PG cells, they are likely to drive tonic release of GABA from PG cells. By contrast, dendrodendritic input from mitral cells, which do not spontaneously burst *in vitro*, may play a larger role in driving GABA release following sensory input.

PG cells contain GABA, and thus activation of these cells will cause dendrodendritic inhibition of ET and mitral/tufted cell dendrites in the glomeruli. PG cell axons also form symmetrical synapses onto the mitral/tufted cell dendrites and onto PG and SA cells (Pinching, A. J. and Powell, T. P., 1971c). Physiological studies support the notion that PG cells receive excitatory input from mitral/tufted cells and ET cells, and in return, make feedforward and feedback inhibitory GABAergic synapses onto these cells (Shepherd, G. M. and Greer, C. A., 1998; Hayar, A. *et al.*, 2004b). Such inhibition is thought to be primarily mediated by $GABA_A$ receptors. ET cells exhibit spontaneous bursts of IPSCs, indicating that these are tonically inhibited by GABAergic inputs (Figure 11) (Hayar, A. *et al.*, 2005). Spontaneous or ON-evoked EPSCs in ET cells are followed by bursts of IPSCs that are synchronous among ET cells of the same glomerulus. Thus, inhibitory GABAergic input from PG cells may coordinate the activity of ET cells associated with the same glomerulus. Intracellular depolarization of ET cells leads to GABAergic inhibition due to activation of dendrodendritic synapses with PG cells (Murphy, G. J. *et al.*, 2005). Using this paradigm, the feedback inhibition produced by ET cell depolarization was reduced by nimodopine, a blocker of L-type Ca^{2+} channels; nimodipine, however, did not reduce GABA release from PG cells. Subsequent experiments, using paired recordings of PG cells, suggested that GABA exocytosis from these cells is governed primarily by activation of HVA, P/Q-type Ca^{2+} channels. The L-type antagonist nimodipine did not directly alter GABA exocytosis from PG cells, leading to the conclusion that activation of LVA currents can facilitate GABA release from PG cells, but these channels are not directly coupled to GABA exocytosis. These studies and others (Smith, T. C. and Jahr, C. E., 2002) also indicate that PG cells, under certain circumstances, can release GABA onto themselves, and perhaps neighboring PG cells. GABA has been reported to depolarize PG cells at their resting potential, probably due to elevated intracellular chloride concentrations (Siklos, L. *et al.*, 1995; Smith, T. C. and Jahr, C. E., 2002). It was suggested

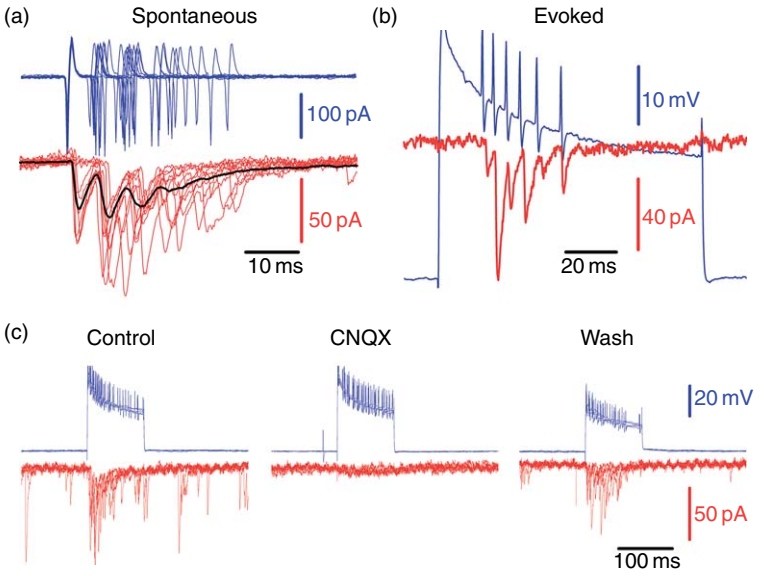

Figure 10 External tufted (ET) cells provide monoexcitatory synaptic input to periglomerular (PG) and short axon (SA) cells. (a) Dual recordings from an ET cell in cell-attached mode (blue traces) and a PG/SA cell in whole-cell voltage-clamp mode (red traces). Left panel (Spontaneous) shows 10 superimposed spontaneous spike burst-triggered traces (triggered on the first spike in the burst); black line is the average of 135 similar traces. Note that spontaneous action currents (blue trace) are accompanied by phase-locked busts of EPSCs (red trace). (b) (Evoked) shows an example of a burst of EPSCs (red trace) evoked by a burst of spikes elicited by extracellular injection of a positive current pulse (700 pA, 100 ms). Note close correspondence between evoked spikes in the ET cell and EPSCs in the SA/PG cell. (d) Recordings from the same two cells shown in panels a and b before (Control), during, and after (Wash) application of CNQX (10 μM). Note that bursts of EPSCs (red traces) in the SA/PG cell elicited by current injection-evoked spikes (blue traces) in the ET cell are completely blocked by CNQX (middle) in a reversible manner (right). CNQX also reversibly abolished spontaneous EPSCs. All panels show five superimposed sweeps. Adapted from Hayar, A., Karnup, S., Ennis, M., and Shipley, M. T. 2004b. External tufted cells: a major excitatory element that coordinates glomerular activity. J. Neurosci. 24, 6676–6685, with permission from The Society for Neuroscience.

that GABA inhibits PG cells by activating a chloride conductance that reduces the neuronal input resistance and shunts excitatory inputs. GABA released from PG cells was recently shown to inhibit other PG cells in the same glomerulus via $GABA_A$ receptors (Murphy, G. J. *et al.*, 2005). Because PG cell dendrites ramify within a restricted portion of a glomerulus, their functional interactions are presumably localized to microdomains of the extensive mitral/tufted cell dendritic arbors, or to nearby JG cells (Kasowski, H. J. *et al.*, 1999).

4.37.2.2.2.(ii) Neuromodulation in the GL

Neuromodulatory systems in the GL include carnosine and certain heavy metals (copper and zinc), and neuromodulatory inputs from centrifugal afferents. Centrifugal inputs are discussed below (see Neurophysiology of Neuromodulatory Inputs to Main Olfactory Bulb). Carnosine, a dipeptide synthesized by ORNs, is localized in ON terminals in the GL and fulfills many criteria for neurotransmitter candidacy. However, no direct postsynaptic actions of carnosine have been revealed to date (MacLeod, N. K. and Straughan, D. W., 1979; Nicoll, R. A. and Alger, B. E., 1980; Frosch, M. P. and Dichter, M. A., 1982; Trombley, P. Q. *et al.*, 1998). Carnosine did not affect currents evoked by glutamate, GABA, or glycine in cultured MOB neurons (Trombley, P. Q. *et al.*, 1998). Because carnosine is a chelator of both zinc and copper, it has been suggested that it might modulate transmission at ON synapses by regulating zinc and copper. Depending on the concentration, both zinc and copper can augment or block responses mediated by NMDA and GABA receptors. Both zinc and copper inhibit *N*-methyl D-aspartate (NMDA) and gamma-aminobutyric acid (GABA) receptor-mediated currents and synaptic transmission in MOB neurons (Trombley, P. Q. and Shepherd, G. M., 1996; Trombley, P. Q. *et al.*, 1998). Carnosine prevented the actions of copper and reduced the effects of zinc. These results suggest that carnosine may indirectly influence glutamate actions on MOB

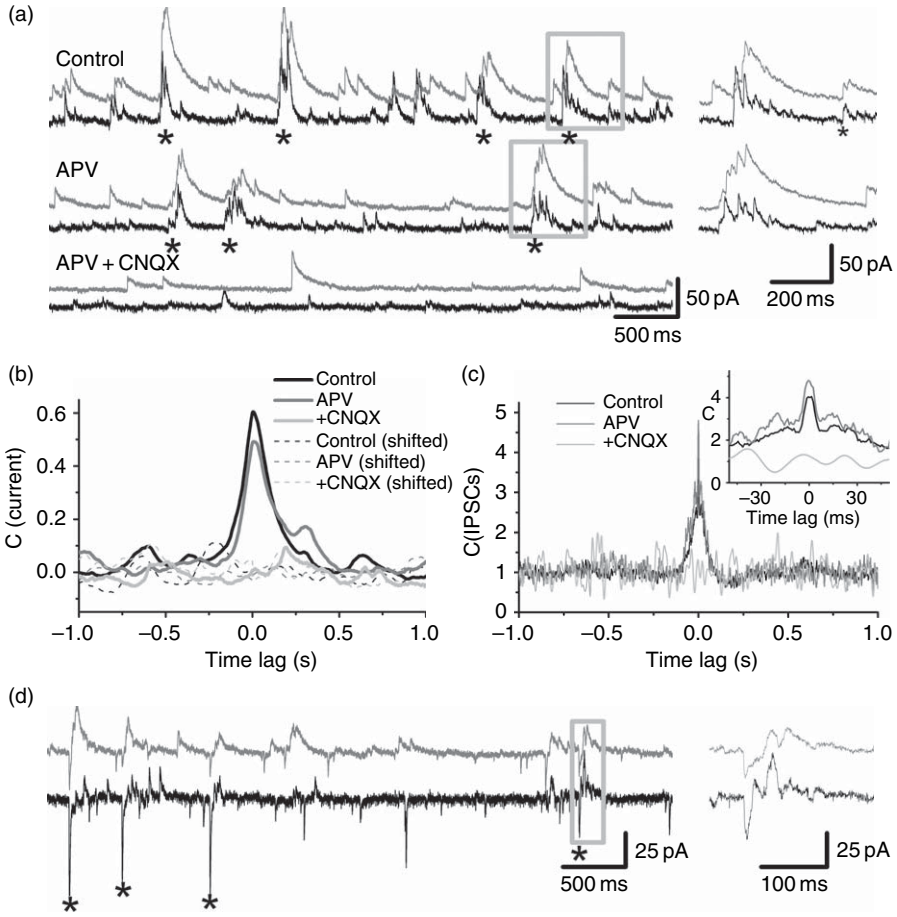

Figure 11 Synchronous bursts of IPSCs in external tufted (ET) cell pairs. All data in this figure were obtained from the same ET cell pair. (a) Simultaneous whole-cell voltage-clamp recordings (holding potential = 0 mV) from two ET cells (gray and black traces, respectively) show synchronous IPSC bursts (asterisks) before and during application of AP5 (50 μM). Note that although AP5 reduced burst frequency, bursts remained synchronous in the two cells. Additional application of CNQX eliminated the IPSC burst synchrony. Areas highlighted in rectangles are shown at faster timescale at right. (b) Membrane current cross-correlograms (50 s recording samples, 2 ms bins) in control, APV, and after additional application of CNQX. Note the significant peak at zero lag time in control and APV. There was no significant correlation after application of CNQX. The 99.73% confidence limit was determined by cross-correlating traces shifted by 5 s (dashed traces). (c) Cross-correlogram of the IPSC trains (5 min recording samples, 1 ms bins) show a significant narrow peak (see inset) at zero time lag, indicating synchronous IPSCs in the two recorded cells. The narrow peak was superimposed on a broader peak corresponding to the longer duration correlated IPSC bursts. CNQX abolished correlation and synchrony of IPSCs. (d) Simultaneous whole-cell voltage-clamp recordings (holding potential = – 30 mV) from the same two ET cells showing synchronous EPSCs followed by IPSC bursts; recording highlighted in rectangle is shown at faster timescale at right. Recordings obtained before the application of synaptic blockers (CNQX, AP5, gabazine) in (a). Adapted from Hayar, A., Shipley, M. T., and Ennis, M. 2005. Olfactory bulb external tufted cells are synchronized by multiple intraglomerular mechanisms. J. Neurosci. 25, 8197–8208, with permission from The Society for Neuroscience.

neurons by modulating the effects of synaptically released zinc and copper. What roles might carnosine, zinc, and copper play in olfactory processing? At present, there are no clear answers to this question. Is carnosine, like other peptide transmitters, preferentially released by high frequencies of ON activity? If so, carnosine may be preferentially released during intense odor stimulation. Zinc is known to be preferentially released during high-frequency neural activity. There are neurotoxic effects of zinc and copper, and Trombley (Horning, M. S. *et al.*, 2000) has speculated that carnosine, by preventing the actions of these metals, may serve an important neuroprotective function, perhaps to protect MOB neurons during intense or high-frequency activity.

4.37.2.3 Electrophysiology of Interglomerular Circuitry

Interglomerular interactions are poorly understood. As noted above, SA cells frequently have multiple dendrites (three to five) that extend over several (two to four) glomeruli (Aungst, J. L. *et al.*, 2003). Thus, these cells may receive odor information from multiple glomeruli. These cells do not receive direct ON input, but instead appear to receive olfactory input indirectly from ET and mitral/tufted cells (Hayar, A. *et al.*, 2004b). In turn, SA cells give rise to an axon that extends for considerable distances (~0.85 mm) in the GL (Aungst, J. L. *et al.*, 2003). Imaging studies suggest that the SA cells may be involved in lateral inhibition between glomeruli. Stimulation of the GL was reported to produce monosynaptic excitation of most ET and PG cells neurons in neighboring glomeruli mediated by activation of ionotropic glutamate receptors (Aungst, J. L. *et al.*, 2003). This suggests the intriguing possibility that SA cells are excitatory. Further, a prepulse to one glomerulus inhibited ON-evoked excitation of mitral cells in another glomerulus. It was concluded that the net functional effect of SA cell activation is to excite PG cells in other glomeruli, causing the release of GABA and inhibition of mitral cell responses to ON input. Taken together, these findings suggest that SA cells represent a major neural element for interglomerular interactions and that these cells may provide a substrate for center-surround inhibition – a common mechanism to enhance stimulus contrast in sensory circuits.

4.37.3 Neurophysiology of External Plexiform Layer

4.37.3.1 Tufted Cells

Tufted cells are the most numerous cells of the EPL. Three subclasses of tufted cells are recognized based on location in the EPL: superficial, middle, and deep tufted cells (Cajal, R. S. Y., 1890; Pinching, A. J. and Powell, T. P., 1971a; Macrides, F. and Schneider, S. P., 1982; Orona, E. *et al.*, 1984). Like ET cells and mitral cells, tufted cells of the mammalian EPL have one (or rarely several) apical dendrite(s) ending in a glomerular tuft (Cajal, R. S. Y., 1890). Like mitral cells, their apical dendrites receive ON input, and they form reciprocal dendrodendritic synapses with the dendrites of PG and SA cells. Their lateral dendrites ramify in the EPL and form dendrodendritic synapses with GCs and other inhibitory interneurons within the EPL. The neurophysiology of dendrodendritic interactions between mitral/tufted cells and GCs in the EPL is discussed below. Axonal projections of middle and deep tufted cells are similar, but not identical, to those of mitral cells (Schoenfeld, T. A. and Macrides, F., 1984; Schoenfeld, T. A. *et al.*, 1985). The local axon collaterals of tufted cells course mainly in the IPL. The projections of tufted cells beyond the MOB terminate densely in the anterior olfactory nucleus and, to a lesser extent, in other rostral olfactory cortical structures (Schoenfeld, T. A. *et al.*, 1985; Scott, J. W., 1986). Few tufted cell axons project into more caudal POC regions.

Tufted cells utilize glutamate as their principle transmitter (Liu, C. J. *et al.*, 1989; Christie, J. M. *et al.*, 2001), but they also stain for a number of other substances, including cholecystokinin (CCK). *In vivo* electrophysiological recordings have shown that the sensitivity of tufted cell subtypes to ON stimulation is correlated with the depth of the lateral dendrites within the EPL. The more superficial tufted cells are more easily excited by ON stimulation than the deeper tufted cells (Schneider, S. P. and Scott, J. W., 1983; Wellis, D. P. *et al.*, 1989; Ezeh, P. I. *et al.*, 1993). In response to odor stimulation, superficially located tufted cells also exhibit more prolonged excitation than mitral cells (Luo, M. and Katz, L., 2001). More recent studies have reported that tufted cells can be excited for up to several minutes following odorant presentation (Luo, M. and Katz, L., 2001). Thus, anatomically distinct tufted cell subtypes appear to be functionally distinct. In slices, tufted cells have been observed to exhibit spontaneous and ON-evoked bursting activity somewhat similar to that of ET cells (Hamilton, K. A. *et al.*, 2005). The extent to which such bursting varies among different tufted cell subtypes, as well as the mechanisms generating bursting, is unknown.

Many superficial tufted cells contain CCK (Seroogy, K. B. *et al.*, 1985), and their axons give rise to a reciprocal network, the intrabulbar association system (IAS) that connects lateral and medial regions of each MOB (Schoenfeld, T. A. *et al.*, 1985). The axons of the IAS travel to the opposite side of the bulb and terminate on the apical dendrites of GCs coursing through the IPL en route to the EPL (Liu, W. L. and Shipley, M. T., 1994). The IAS projection exhibits a high degree of point-to-point specificity. The IAS projections from tufted cells associated with a single glomerulus preferentially target the IPL deep to the second glomerulus on the other side of MOB

(Belluscio, L. *et al.*, 2002; Lodovichi, C. *et al.*, 2003). Thus, the IAS appears to modulate the activities of subsets of MOB neurons receiving input from ORNs expressing the same receptor, on opposite sides of the MOB. CCK typically is excitatory, and therefore the IAS may depolarize GCs.

4.37.3.2 EPL Interneurons

The EPL contains anatomically and neurochemically heterogeneous subtypes of intrinsic interneurons (for review, see Ennis, M. *et al.*, 2007). Many EPL interneurons stain for GABA and are therefore presumed to be inhibitory (Mugnaini, E. *et al.*, 1984; Gall, C. M. *et al.*, 1987; Kosaka, T. *et al.*, 1987c; Ohm, T. G. *et al.*, 1990). EPL interneuron subtypes are neurochemically diverse and stain for a number of neurotransmitter markers, including NADPH diaphorase (Scott, J. W. *et al.*, 1987; Villalba, R. M. *et al.*, 1989; Alonso, J. R. *et al.*, 1995), substance P (Baker, H., 1986; Wahle, P. *et al.*, 1990), enkephalin (Bogan, N. *et al.*, 1982; Davis, B. J. *et al.*, 1982), NPY (Gall, C. *et al.*, 1986; Scott, J. W. *et al.*, 1987; Sanides-Kohlrausch, C. and Wahle, P., 1990a), neurotensin and somatostatin (Matsutani, S. *et al.*, 1988), and VIP (Gall, C. *et al.*, 1986; López-Mascaraque, L. *et al.*, 1989; Sanides-Kohlrausch, C. and Wahle, P., 1990b; Nakajima, T. *et al.*, 1996). The role of these transmitters in the function of EPL interneurons is not known. EPL interneurons are thought to interact chiefly with mitral/tufted cell dendrites (López-Mascaraque, L. *et al.*, 1990; Nagayama, S. *et al.*, 2004) and possibly GC dendrites (Schneider, S. P. and Macrides, F., 1978). Combined morphological and electrophysiological analyses showed that GABAergic EPL interneurons with highly varicose dendrites are excited polysynaptically by ON stimulation, most likely via input from nearby mitral/tufted cells (Hamilton, K. A. *et al.*, 2005). The interneurons exhibit high levels of spontaneous glutamatergic synaptic activity mediated by AMPA/kainate receptors, consistent with GluR1 AMPA receptor subunit staining in these cells (Petralia, R. S. and Wenthold, R. J., 1992; Giustetto, M. *et al.*, 1997; Montague, A. A. and Greer, C. A., 1999; Hamilton, K. A. and Coppola, D. M., 2003). Many EPL interneurons have dendrites that spanned several adjacent glomeruli, suggesting that they may provide localized inhibition of mitral/tufted cells that are topographically related to overlying glomeruli (Hamilton, K. A. *et al.*, 2005).

4.37.4 Neurophysiology of Mitral Cells

4.37.4.1 Anatomical Features

Deep to the EPL is the MCL, a thin layer that contains the somata of mitral cells as well as numerous GCs (Cajal, R. S. Y., 1911a; 1911b). In fact, there are ~40,000 mitral cells (Meisami, E., 1989) and ~100,000 GCs in the MCL (Frazier, L. L. and Brunjes, P. C., 1988). Thus, mitral cells comprise less than one-half of the cells in the MCL. Together with tufted cells, mitral cells are the major class of output cells of the bulb. As noted above, mitral cells extend a single apical dendrite into one glomerulus. There are about 25 mitral cells (and 50 tufted cells) associated with a single glomerulus (Cajal, R. S. Y., 1911a; 1911b; Allison, A., 1953). The apical dendrites are synaptically contacted by ON terminals (Price, J. L. and Powell, T. P. S., 1970a; Shepherd, G. M., 1972). The secondary or lateral dendrites of mitral cells ramify in the EPL where they may extend up to 1–2 mm. These lateral dendrites participate in dendrodendritic synapses with dendrites of GCs, as reviewed below (see Dendrodendritic Transmission Between Mitral/Tufted Cells and Granule Cells). Mitral cells have been subdivided into two classes, Type I and Type II, based on extension of dendrites into the deep or superficial parts of the EPL, respectively (Orona, E. *et al.*, 1984). Type II mitral cells are more easily excited by ON stimulation than Type I mitral cells (Schneider, S. P. and Scott, J. W., 1983; Wellis, D. P. *et al.*, 1989; Ezeh, P. I. *et al.*, 1993). Mitral cell lateral dendrites receive centrifugal axon inputs and inputs from EPL interneurons (Jackowski, A. *et al.*, 1978; Toida, K. *et al.*, 1996). Mitral cells give off axon collaterals, which terminate within the bulb, in the IPL and GCL (Price, J. L. and Powell, T. P. S., 1970c; Mori, K. *et al.*, 1983), or exit the MOB and innervate a number of olfactory-related brain regions collectively known as the POC. Mitral (and tufted) cells are glutamatergic, and the neuropeptide corticotropin-releasing factor (CRF) has been demonstrated in mitral and some tufted cells. Substance P has been detected in approximately one-half of mitral cells by in situ hybridization (Warden, M. K. and Young, W. S., 1988), but they do not stain for substance P immunocytochemistry (Inagaki, S. *et al.*, 1982; Shults, C. W. *et al.*, 1984; Baker, H., 1986).

4.37.4.2 Spontaneous Discharge and Intrinsic Membrane Properties

In vivo extracellular recording studies in anesthetized animals indicate that most mitral cells fire at fairly

high spontaneous rates (6–30 Hz; mean rate, ~18 Hz) (Chaput, M. and Holley, A., 1979; Chaput, M., 1983; Yu, G.-Z. *et al.*, 1993; Jiang, M. R. *et al.*, 1996). They also exhibit periodic, long-duration (several minutes) tonic increases and decreases in firing rates that may be related to anesthesia (Yu, G.-Z. *et al.*, 1993; Jiang, M. R. *et al.*, 1996); mitral cells are less responsive to ON during the periods of reduced spontaneous activity. In awake rats, mitral cells firing rates range from 1 to 33 Hz with a mean rate of 12 Hz (Kay, L. M. and Laurent, G., 1999). A detailed consideration of mitral cell odor responses, receptive fields, and plasticity is beyond the scope of this chapter, and readers are referred to recent work in this area (Kashiwadani, H. *et al.*, 1999; Kay, L. M. and Laurent, G., 1999; Luo, M. and Katz, L., 2001; Fletcher, M. L. and Wilson, D. A., 2003; Nagayama, S. *et al.*, 2004; Mori, K. *et al.*, 2006).

Mitral cell spontaneous firing patterns and odor responses *in vivo* are modulated as a function of the respiratory cycle. Recent patch clamping studies in anesthetized rodents has provided new information on properties of mitral spontaneous and odor-evoked discharge. Mitral cells exhibit subthreshold membrane potential oscillations or action potentials synchronized to or modulated by respiration, which occurs in the theta frequency range, 1–12 Hz (Philpot, B. D. *et al.*, 1997; Chalansonnet, M. and Chaput, M. A., 1998; Kay, L. M. and Laurent, G., 1999; Charpak, S. *et al.*, 2001; Luo, M. and Katz, L., 2001; Debarbieux, F. *et al.*, 2003; Margrie, T. W. and Schaefer, A. T., 2003). The peak depolarization of the membrane potential oscillation coincides with the peak of the inhalation phase (Margrie, T. W. and Schaefer, A. T., 2003). The rhythmic membrane potential oscillations are blocked by glutamate receptor antagonists, demonstrating that they are synaptically mediated (Margrie, T. W. and Schaefer, A. T., 2003). Combined intrinsic imaging of glomerular odor responses and intracellular recordings from mitral cells suggest that mitral cells recorded below odor responsive glomeruli are excited by the odor, whereas those cells distant from the activated glomeruli show no response or are inhibited (Luo, M. and Katz, L., 2001). In responses to excitatory odors, mitral cells typically generate EPSPs and spikes that are synchronized to the inspiratory phase of respiration which occurs in the theta frequency range (Charpak, S. *et al.*, 2001; Margrie, T. W. *et al.*, 2001; Cang, J. and Isaacson, J. S., 2003; Debarbieux, F. *et al.*, 2003; Margrie, T. W. and Schaefer, A. T., 2003). EPSP amplitudes vary proportionately with the strength of the odor stimulus, and spikes are often launched from the rising phase of odor-evoked EPSPs (Cang, J. and Isaacson, J. S., 2003; Margrie, T. W. and Schaefer, A. T., 2003). The latency of the first spike following odor stimuli is inversely proportional to the number of spikes per respiratory cycle such that shorter latencies are observed when spike bursts are elicited (Cang, J. and Isaacson, J. S., 2003; Margrie, T. W. and Schaefer, A. T., 2003). This suggests that the initial spike latency may provide information about the strength of sensory input; that is, the concentration of odors. Sufficiently strong odor stimulation triggers a spike burst, with spikes in the burst occurring within the β–γ frequency range (20–60 Hz) (Debarbieux, F. *et al.*, 2003). The interburst spike frequency is constant across bursts that vary in the number of spikes (Margrie, T. W. and Schaefer, A. T., 2003). This suggests that the instantaneous spike frequency probably is not modulated by network-driven factors. Mitral cells also exhibit inhibitory responses to odors (Luo, M. and Katz, L., 2001; Margrie, T. W. *et al.*, 2001; Cang, J. and Isaacson, J. S., 2003). The strength of odor-evoked inhibitory postsynaptic potentials (IPSPs) does not vary with the concentration of the odor stimulus (Cang, J. and Isaacson, J. S., 2003). However, the IPSP amplitudes are larger during the initial respiratory cycle compared to subsequent cycles in the presence of an odorant.

In slices, mitral cell spontaneous discharge is more modest (1–6 Hz, mean, 3 Hz), presumably because tonic sensory input is absent (Ennis, M. *et al.*, 1996, Ciombor, K. J. *et al.*, 1999; Heyward, P. M. *et al.*, 2001). Mitral cell spontaneous firing is intrinsically generated and persists in the presence of blockers of ionotropic glutamate and GABA receptors (Ennis, M. *et al.*, 1996; Heyward, P. M. *et al.*, 2001). Patch clamp recordings have revealed that mitral cells exhibit intrinsic membrane bistability (Heyward, P. M. *et al.*, 2001; Heinbockel, T. *et al.*, 2004). They spontaneously alternate between a perithreshold upstate membrane potential and a more hyperpolarized (approximately −10 mV) downstate membrane potential (Figure 13). Bistability is typically encountered in mitral cells recorded in the depth of the slice (>70 μm from the surface) and may be absent in superficially located cells. Spontaneous or ON-evoked spikes are readily launched from the upstate, and a spike afterhyperpolarization or a hyperpolarization induced by an IPSP or current injection of sufficient amplitude resets the cell to the downstate.

In the downstate, more robust ON input is necessary to trigger spikes. The upstate is also characterized by high-frequency (10–50 Hz) subthreshold membrane potential oscillations that appear to be mediated by a balance between opposing K^+ currents and TTX-sensitive Na^+ currents (Desmaisons, D. *et al.*, 1999; Heyward, P. M. *et al.*, 2001; Balu, R. *et al.*, 2004). Inhibitory synaptic input (e.g., IPSPs) can reset the phase of the oscillations and the timing of mitral cell spikes (Desmaisons, D. *et al.*, 1999). The downstate appears to be maintained by slowly inactivating outward currents (e.g., K^+ currents), and the transition from the downstate to the upstate is due to inactivation of the outward currents and activation of regenerative voltage-dependent inward currents (e.g., TTX-sensitive, persistent Na^+ currents). The transition from the upstate to the downstate may reflect voltage-dependent inactivation of inward currents and activation of outward currents initiated by action potentials. Other aspects of mitral cell spontaneous activity are discussed below in Oscillations and Synchrony in Main Olfactory Bulb.

Further studies indicated that mitral cell-evoked activity is regulated by interactions between subthreshold TTX-sensitive Na^+ currents and by 4-amonipyridine (4-AP)-sensitive K^+ currents, such as transient outward or I_D currents (Balu, R. *et al.*, 2004). In response to sustained depolarization pulses, mitral cells generate intermittent spike clusters at 20–40 Hz, with clusters occurring with variable timing at theta frequencies (1–5 Hz). Brief repolarizations to recover inactivated Na^+ currents during sustained depolarizing pulses eliminated spike variability. Brief depolarizing pulses or simulated EPSPs mimicking rhythmic ON input during sniffing elicited highly precise spike clusters. The first EPSP frequently failed to elicit spikes, but decreased the spike threshold for subsequent EPSPs. 4-AP caused spikes to be triggered by the first EPSP but impaired precise spike timing to subsequent EPSPs. 4-AP also abolished intermittent or clustered firing during sustained depolarizations. Taken together, these findings suggest that intrinsic properties of mitral cells yield variable spiking responses to sustained depolarizations but allow temporally precise or phase-locked spiking responses to brief phasic input. Based on this, it has been suggested that mitral cells may be functionally analogous to high-pass filters, preferentially responding to phasic events that occur at theta frequencies (Balu, R. *et al.*, 2004).

Mitral cells also exhibit afterhyperpolarizations mediated by Ca^{2+}-dependent K^+ conductances (Maher, B. J. and Westbrook, G. L., 2005). Step depolarization of mitral cells to +10 mV elicits outward currents that are attenuated by Cd^{2+} or the SK K^+ channel antagonist apamin. This current was reported to be absent in GCs. The SK current could be activated by Ca^{2+} influx via NMDA receptors or voltage-dependent Ca^{2+} channels. Apamin application increased the depolarization-evoked firing frequency of mitral cells. Other studies indicate that mitral cells lack, or have very weak, H-type currents (Djurisic, M. *et al.*, 2004). Mitral cells also express Kv1.3, a rapidly activating, moderately slow inactivating type of voltage-gated K^+ channels (Fadool, D. A. *et al.*, 2004). Mitral cells from Kv1.3-knockout mice have more depolarized resting potentials and smaller, broader spikes in comparison with those from wildtype mice.

4.37.4.3 Dendritic Spike Propagation

In vivo, odors have been reported to elicit fast prepotentials in mitral cells thought to represent truncated spikes generated in the apical dendrites (see Mori, K., 1987 for review). Similar fast prepotentials have been observed in slices (Chen, W. R. and Shepherd, G. M., 1997). More recent findings in MOB slices demonstrate that both the apical and lateral dendrites of mitral cells actively propagate action potentials. Spike elicited at the soma backpropagate nondecrementally along the apical dendrite and vice versa (Bischofberger, J. and Jonas, P., 1997; Chen, W. R. *et al.*, 1997; Isaacson, J. S. and Strowbridge, B. W., 1998; Debarbieux, F. *et al.*, 2003). The ability of the apical dendrite to generate spikes is due to the presence of TTX-sensitive Na^+ channels (Bischofberger, J. and Jonas, P., 1997). These studies suggest that with sufficiently strong ON input, spikes can be initiated in the apical dendrite and conducted to the soma without decrement. However, the site of spike initiation can be controlled by inhibitory inputs to the soma. With leak levels of ON stimulation, spikes are preferentially triggered at the soma, but this can be blocked by IPSPs at the soma or proximal segments of the lateral dendrite (Chen, W. R. *et al.*, 1997; Djurisic, M. *et al.*, 2004). With stronger levels of ON input, inhibitory inputs to the soma shifted the spike initiation site to the apical dendrite. ON-evoked EPSPs by contrast are decremental, and they decrease in amplitude by ~30% over a 300-μm distance in the apical dendrite (Djurisic, M. *et al.*, 2004).

Similar studies demonstrate actively propagating Na^+ spikes in mitral cell lateral dendrites

(Margrie, T. W. *et al.*, 2001; Xiong, W. and Chen, W. R., 2002). This suggests that spikes in single mitral cells, via activation of mitral to granule synapses, could conceivably inhibit mitral cells at considerable distances throughout the MOB. However, whether the spike propagation is nondecremental along the full length of the lateral dendrite is unclear as propagation has been reported to be attenuating (Margrie, T. W. *et al.*, 2001; Lowe, G., 2002; Christie, J. M. and Westbrook, G. L., 2003) or nonattenuating (Margrie, T. W. *et al.*, 2001; Xiong, W. and Chen, W. R., 2002; Debarbieux, F. *et al.*, 2003). Spike attenuation was reported to be caused by activation of A-type K^+ channels in the lateral dendrites (Christie, J. M. and Westbrook, G. L., 2003). Regenerative Ca^{2+} currents do not appear to play a role in dendritic spikes (Charpak, S. *et al.*, 2001; Margrie, T. W. *et al.*, 2001; Xiong, W. and Chen, W. R., 2002; Christie, J. M. and Westbrook, G. L., 2003). Local synaptic inhibitory input (GABAergic IPSPs) can block propagation of spikes in the lateral dendrite (Margrie, T. W. *et al.*, 2001; Lowe, G., 2002; Xiong, W. and Chen, W. R., 2002). Such inhibition is more influential when it occurs at the soma and/or proximal dendrites. Thus, inhibitory input to the soma and lateral dendrites may spatially constrain the range and magnitude of lateral inhibition (see also Dendrodendritic Inhibition).

4.37.4.4 Modulation by mGluRs and DA

In dissociated cultured rat and frog MOB neuronal preparations, Group I mGluRs increased Ca^{2+} release from internal stores in mitral/tufted cells as well as in MOB interneurons (Geiling, H. and Schild, D., 1996; Carlson, G. C. *et al.*, 1997), or it depolarized and increased the frequency of miniature excitatory postsynaptic currents in mitral cells (Schoppa, N. E. and Westbrook, G. L., 1997). Other studies indicate that activation of Group III mGluRs with AP4 inhibits Ca^{2+} currents in mitral cells and presynaptically decreases mitral cell to GC synaptic transmission (Trombley, P. Q. and Westbrook, G. L., 1992). More recent studies in rat and mouse MOB slices demonstrate that activation of mGluR1 directly depolarizes and increases the firing of MCs and that these effects persist in the presence of blockers of fast synaptic transmission (Figure 12) (Heinbockel, T. *et al.*, 2004). The same study showed that mGluR1 induces a voltage-dependent inward current consisting of multiple components. mGluR1 antagonists also altered mitral cell membrane potential bistability, increasing the duration of the upstates and downstates, and substantially attenuated ON-evoked spikes (Figure 13). These findings suggest that endogenous glutamate tonically modulates MC excitability and responsiveness to ON input via activation of mGluR1. Although DA has no direct effect on resting membrane properties of mitral cells, pharmacological activation of D2 receptors was found to reduce glutamate release from mitral cells onto olfactory bulb interneurons in culture via inhibition of N and/or P/Q HVA Ca^{2+} channels (Davila, N. G. *et al.*, 2003).

4.37.5 Neurophysiology of Neurons in the Granule Cell Layer

4.37.5.1 Neuron Types of the GCL

GCs are axon-less cells with small cell bodies that are mostly tightly packed into row-like aggregates of three to nine somata in the GCL (Reyher, C. K. *et al.*, 1991). More superficially located GCs are also found mixed with mitral cell bodies within the MCL. Most GCs have an apical dendrite that ramifies within the EPL and shorter basal dendrites that ramify within the GCL. A differential sublaminar distribution has been observed for the dendrites of superficial and deep GCs. The apical dendrites of superficial GCs have very dense spines, and they terminate within both the superficial and deep portions of the EPL. By contrast, the apical dendrites of deeper GCs terminate preferentially within the deep EPL (Orona, E. *et al.*, 1983; Greer, C. A., 1987). Most GCs contain GABA (Ribak, C. E. *et al.*, 1977), but some contain enkephalin (Bogan, N. *et al.*, 1982; Davis, B. J. *et al.*, 1982). GC apical dendrites receive asymmetrical synapses from, and make symmetrical synapses onto, mitral/tufted cells. GCs also receive asymmetrical synapses from a variety of centrifugal afferents, including inputs from neuromodulatory transmitter systems (see Neurophysiology of Neuromodulatory Inputs to Main Olfactory Bulb) and POC (see Neurophysiology of Primary Olfactory Cortical Inputs to Main Olfactory Bulb) (Price, J. L. and Powell, T. P. S., 1970c). Centrifugal fibers arise from neurons in POC (e.g., piriform cortex (PC) and anterior olfactory nucleus) and comprise the bulk of synaptic contacts onto GC somata and proximal dendrites within the GCL (Price, J. L. and Powell, T. P. S., 1970c). GCs also receive synapses from the collateral branches of mitral and tufted cell axons, as well as inputs from

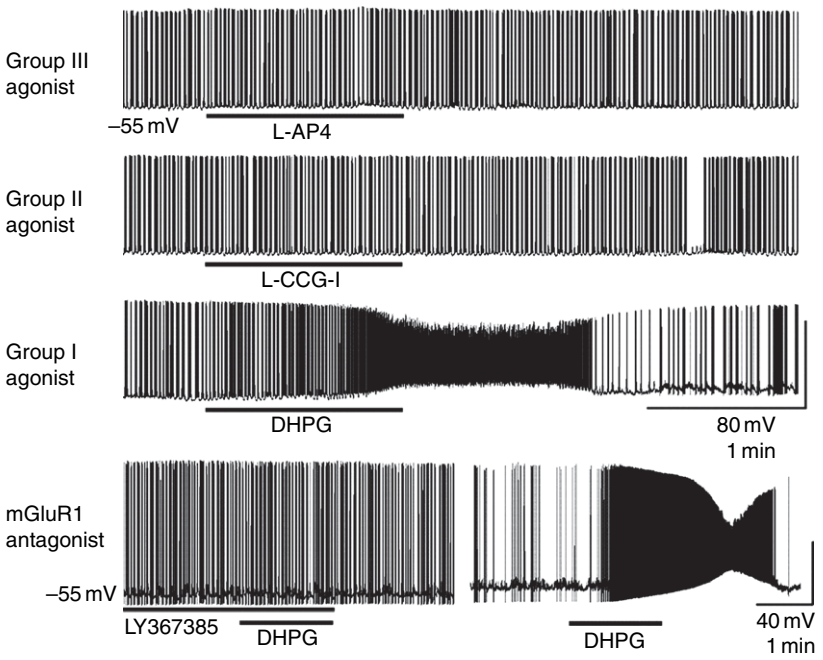

Figure 12 The group I mGluR agonist (RS)-3,5-dihydroxyphenylglycine (DHPG) depolarizes and increases the firing of mitral cells. Mitral cells were activated by group I, but not group II or III, mGluR agonists. Bath application of the group III mGluR agonist L(+)-2-amino-4-phosphonobutyric acid (AP4; 100 μM) or the group II mGluR agonist (2S,3S,4S)-CCG/(2S,1'S,2'S)-2-(carboxycyclopropyl)glycine (L-CCG-I; 20 μM) did not alter the membrane potential or firing rate of this mouse mitral cell (MC) in current clamp recordings. The same cell was activated by the selective group I agonist DHPG. The selective mGluR1 antagonist ({alpha}S)-{alpha}-amino-{alpha}-[(1S,2S)-2-carboxycyclopropyl]-9H-xanthine-9-propanoic acid (LY367385, 100 μM) blocked the actions of the group I mGluR agonist DHPG (50 μM) in another mouse MC. After washout (>15 min), reapplication of DHPG robustly depolarized and increased MC spontaneous discharge. All experiments were performed in the presence of blockers of fast synaptic transmission: CNQX (10 μM), APV (50 μM), and gabazine (5 μM). Reprinted from Heinbockel, T., Heyward, P., Conquet, F., and Ennis, M. 2004. Regulation of main olfactory bulb mitral cell excitability by metabotropic glutamate receptor mGluR1. J. Neurophysiol. 92, 3085–3096, with permission from The American Physiological Society.

Golgi, Cajal, and Blanes cells (Price, J. L. and Powell, T. P. S., 1970c).

The IPL and GCL also contain several interneuron subtypes (short-axon cells; Golgi, Cajal, and Blanes cells) that have dendrites and axons that ramify within the EPL, MCL, and GCL (Price, J. L. and Powell, T. P. S., 1970b; Schneider, S. P. and Macrides, F., 1978; Cajal, R. S. Y., 1890; Van Gehuchten, L. E. and Martin, A., 1891; Blanes, T., 1898; López-Mascaraque, L. *et al.*, 1990). These cells stain for a number of transmitters, including GABA, VIP, NPY, enkephalin, and somatostatin (see Ennis, M. *et al.*, 2007 for review). With the exception of Blanes cells, very little is known about the functions of the deep interneurons, but all are presumed to be inhibitory. Blanes cells have numerous dendrites emerging from all sides of the soma. The axons from these cells can extend considerable distances, but they typically remain within the GCL (Cajal, R. S. Y., 1911a; 1911b; Pressler, R. T. and Strowbridge, B. W., 2006). The anatomical features of other interneurons in the IPL/GCL are reviewed elsewhere (Ennis, M. *et al.*, 2007).

4.37.5.2 Neurophysiology of GCs

In vivo and in slice preparations, GCs spontaneous spiking is relatively infrequent, probably due to their relatively hyperpolarized resting potential (−65 to −75 mV) and appears to be driven primarily by spontaneous glutamatergic input (Wellis, D. P. and Scott, J. W., 1990; Cang, J. and Isaacson, J. S., 2003; Zelles, T. *et al.*, 2006; Heinbockel, T. *et al.*, 2007). Synaptic input or direct depolarization can elicit Na^+ and Ca^{2+} spikes in GCs (Halabisky, B. *et al.*, 2000; Pinato, G. and Midtgaard, J., 2003; 2005; Egger, V. *et al.*, 2005). By contrast to mitral cells, odor-evoked responses in GCs attenuate rapidly after the first respiratory cycle (Cang, J. and Isaacson, J. S., 2003).

GCs express Ca^{2+} currents which activate at approximately −60 mV and peak at 0–5 mV (Chen, W. R.

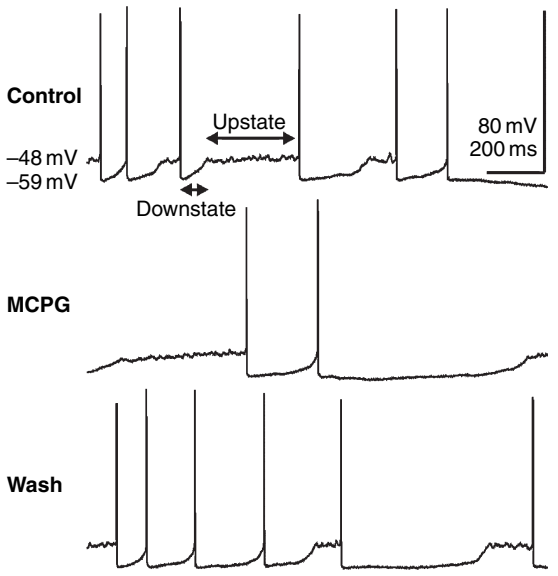

Figure 13 Activation and blockade of mGluRs modulates mitral cell (MC) spontaneous activity and membrane bistability. Upper trace: Current clamp recording showing membrane bistability in a rat MC. Middle trace: Bath application of MCPG (500 μM) reduced the firing frequency of the MC and prolonged the upstates and downstates. Bottom trace: the effects of MCPG were reversible on washout. Reprinted from Heinbockel, T., Heyward, P., Conquet, F., and Ennis, M. 2004. Regulation of main olfactory bulb mitral cell excitability by metabotropic glutamate receptor mGluR1. J. Neurophysiol. 92, 3085–3096, with permission from The American Physiological Society.

et al., 2000; Isaacson, J. S. and Vitten, H., 2003). These currents involve both LVA T-type Ca^{2+} currents and HVA Ca^{2+} currents (Isaacson, J. S. and Vitten, H., 2003). T-type currents can be activated by depolarization subthreshold for spike initiation and have been linked to GABA release from GCs (Egger, V. *et al.*, 2003). Small subthreshold EPSPs seem to produce Ca^{2+} transients restricted to dendritic spines (Egger, V. *et al.*, 2005). These Ca^{2+} transients appear to involve several sources, including LVA and HVA Ca^{2+} channels, NMDA receptors, and Ca^{2+}-induced Ca^{2+} release (Egger, V. *et al*, 2005). Sufficiently large EPSPs can trigger an all-or-none LTS that propagates throughout the GC dendrites (Egger, V. *et al.*, 2005). LTSs in GC soma have been described in amphibians (Pinato, G. and Midtgaard, J., 2003; 2005).

GC activity is strongly regulated by several K^+ conductances. They have a strong transient A-type K^+ current, I_A (Schoppa, N. E. and Westbrook, G. L., 1999). I_A in these cells activates at approximately −44 mV, at or near the threshold for spike generation (−47 mV). Many I_A channels are only half-inactivated at GC resting membrane potential, and thus are available to affect depolarizing inputs (Schoppa, N. E. and Westbrook, G. L., 1999). Blockade of I_A with 4-AP decreases the lag or delay for evoked spikes. The I_A channels are expressed in the distal dendrites of GCs where they tend to counter brief depolarizing synaptic inputs. BK-type or high-conductance Ca^{2+}-activated K^+ currents involved in spike repolarization of afterhyperpolarization are engaged in GCs by strong depolarization or activation of NMDA receptors (Isaacson, J. S. and Murphy, G. J. 2001). Anatomically, gap junctions have been reported among GCs (Reyher, C. K. *et al.*, 1991), although electrophysiological studies found no evidence for electrotonic coupling (Schoppa, N. E., 2006). GCs in the GCL are potently activated by mGluR1 agonists, which depolarize and increase the firing rate of these cells (Heinbockel, T. *et al.*, 2007). By contrast, mGluR1 antagonists reduce mitral/tufted cell-evoked excitation of GCs.

4.37.5.3 Neurophysiology of Blanes Cells

Blanes cells are neurophysiologically distinct from GCs (Pressler, R. T. and Strowbridge, B. W., 2006). They have lower input resistance, more depolarized resting potential, and more hyperpolarized spike threshold than GCs. Stimulation of Blanes cells elicits monosynaptic GABAergic IPSPs in GCs, but Blanes cells do not receive reciprocal input from GCs. These cells generate prominent afterdepolarizations (ADPs) after action potentials that are triggered by Ca^{2+} influx through non-L-type channels. ADPs were suppressed by flufenamic acid, a blocker of nonspecific cation currents (I_{CAN}). Taken together, these findings suggest that the ADP is mediated by a Ca^{2+}-dependent I_{CAN}. Brief depolarization triggers unusually prolonged (up to 44 min) persistent spiking in Blanes cells. Persistent firing could also be triggered by excitatory synaptic input elicited by stimulation in the GCL or the GL. Stimuli that evoked persistent firing in Blanes cells also produced prolonged barrages of IPSCs in GCs. These findings indicate that Blanes cells play a major role in prolonged modulation of the excitability state of GCs, which in turn would impact on the activity of mitral/tufted output neurons. Blanes cells preferentially target the basal dendrites and somata of GCs, and like GCs, Blanes cells may receive centrifugal feedback projections from POC. If so, then direct

activation of GCs by POC inputs may be followed by prolonged Blanes cell-mediated inhibition of GCs. Thus, the activity state of Blanes cells may provide a gate on excitatory feedback projections from POC to GCs, which in turn, would modulate GC inhibition of mitral/tufted cells.

4.37.6 Dendrodendritic Transmission Between Mitral/Tufted Cells and Granule Cells

4.37.6.1 Overview of Mitral/Tufted Cell–GC Dendrodendritic Interactions

The majority of synapses of the EPL are between the lateral dendrites of mitral/tufted cells and the dendrites of GCs. Most of the synapses are: (1) asymmetrical synapses from the mitral/tufted cell lateral dendrites onto GC dendrites, and (2) symmetrical synapses from the spines (gemmules) of GC dendrites onto the mitral/tufted cell lateral dendrites (Price, J. L. and Powell, T. P. S., 1970b; 1970c; 1970d). These synapses are mostly reciprocal (Hirata, Y., 1964; Rall, W. *et al*., 1966; Price, J. L. and Powell, T. P. S., 1970d; Woolf, T. B. *et al*., 1991) and therefore occur in roughly equal proportion (Jackowski, A. *et al*., 1978). One mitral/tufted cell can therefore receive feedback inhibition as well as lateral inhibition from GCs that are excited by other mitral/tufted cells.

4.37.6.2 Excitatory Transmission from Mitral/Tufted Cells to GCs

Spike-evoked Ca^{2+} transients in mitral cells, and presumably glutamate release, is abolished by Cd^{2+} but not Ni^{2+}, indicating that it requires activation of HVA Ca^{2+} channels (Isaacson, J. S. and Strowbridge, B. W., 1998). Intracellular Ca^{2+} buffering in mitral cells indicates that the Ca^{2+} channels that trigger dendritic glutamate release are located nearby active release sites (Isaacson, J. S. and Strowbridge, B. W., 1998). In normal or Mg^{2+}-free extracellular media, stimulation of mitral/tufted cells evokes dual-component EPSCs in GCs, consisting of a fast AMPA receptor component and a slow NMDA receptor component (Isaacson, J. S. and Strowbridge, B. W., 1998; Schoppa, N. E. *et al*., 1998; Aroniadou-Anderjaska, V. *et al*., 1999a; Chen, W. R. *et al*., 2000; Isaacson, J. S., 2001). AMPA receptors in cultured GCs desensitize rapidly and have little or no Ca^{2+} permeability (Blakemore, L. J. and Trombley, P. Q., 2003), suggesting that GC AMPA receptors must include GluR2 subunits, which regulate Ca^{2+} permeability (Jardemark, K. *et al*., 1997). The AMPA receptor synaptic component evoked by mitral/tufted cell input is less effective than the NMDA receptor component in evoking spikes in GCs, especially in Mg^{2+}-free conditions (Schoppa, N. E. *et al*., 1998). As noted above, block of I_A enhances the ability of the AMPA receptor component to trigger spikes in GCs (Schoppa, N. E. and Westbrook, G. L., 1999). Paired-pulse stimulation of mitral cells can produce either facilitation or depression of the GC excitatory response to the second pulse, but on average leads to paired-pulse facilitation (Dietz, S. B. and Murthy, V. N., 2005). With repetitive stimulation trains, mitral to GC responses were suppressed less than GC to mitral cell inhibitory responses. Mitral/tufted cell to GC transmission may be modulated by mGluRs and monoaminergic transmitters (see Section Neurophysiology of Neuromodulatory Inputs to Main Olfactory Bulb). Activation of Group III mGluR was reported presynaptically to decrease mitral cell to GC synaptic transmission (Trombley, P. Q. and Westbrook, G. L., 1992).

4.37.6.3 Inhibitory Transmission from GCs to Mitral/Tufted Cells

Activation of GCs evokes IPSPs/IPSCs in mitral cells mediated by activation of $GABA_A$ receptors (Chen, W. R. *et al*., 2000; Isaacson, J. S. and Vitten, H., 2003; Dietz, S. B. and Murthy, V. N., 2005). Paired-pulse or repetitive activation of GCs typically produces paired-pulse inhibition of mitral cell synaptic responses; that is, the response to the second or subsequent pulses are smaller than that to the first (Isaacson, J. S. and Vitten, H., 2003; Dietz, S. B. and Murthy, V. N., 2005). Pharmacological activation of $GABA_B$ receptors on GCs has been reported to reduce GABA release from these cells via inhibition of HVA Ca^{2+} currents (Isaacson, J. S. and Vitten, H., 2003).

4.37.6.4 Dendrodendritic Inhibition

4.37.6.4.1 Self-inhibition

Intracellular stimulation of single mitral cells in the presence or absence of TTX results in a dendrodendritically mediated feedback IPSPs/IPSCs, that is, self-inhibition or feedback inhibition (Isaacson, J. S. and Strowbridge, B. W., 1998; Schoppa, N. E. *et al*., 1998; Chen, W. R. *et al*., 2000; Halabisky, B. *et al*., 2000; Dietz, S. B. and Murthy, V. N., 2005). Subsequent studies demonstrated that TTX has opposite effects

on self-inhibition that depend upon the strength of the mitral cell depolarizing pulse; that is, the amount of glutamate released by the mitral cell (Halabisky, B. *et al.*, 2000). Short-pulse (2–3 ms) self-inhibition is reduced, whereas long-pulse (>25 ms) inhibition is enhanced, by TTX. The feedback inhibition is of long duration (1–2 s) and consists of a flurry of individual IPSPs/IPSCs. The slow kinetics suggest that the feedback IPSPs/IPSCs is mediated by asynchronous GABA release from multiple GCs (Schoppa, N. E. *et al.*, 1998). In normal extracellular levels of Mg^{2+}, the self-inhibition is reduced to similar levels by AMPA or NMDA receptor antagonism and is abolished when antagonists to both receptors are applied (Isaacson, J. S. and Strowbridge, B. W., 1998). Mg^{2+}-free conditions enhance self-inhibition and cause it to be dominated by activation of NMDA receptors; under these conditions, AMPA receptors have only a minor effect of the magnitude of self-inhibition (Isaacson, J. S. and Strowbridge, B. W., 1998; Schoppa, N. E. *et al.*, 1998; Chen, W. R. *et al.*, 2000; Isaacson, J. S., 2001; Halabisky, B. and Strowbridge, B. W., 2003). Similar findings were obtained for tufted cell self-inhibition (Christie, J. M. *et al.*, 2001). As will be discussed below, lateral inhibition has been reported to be strongly regulated by the I_A current in GCs. Self-inhibition has been reported to be unaffected (Halabisky, B. *et al.*, 2000) or enhanced (Schoppa, N. E. and Westbrook, G. L., 1999; Isaacson, J. S., 2001) by blockers of I_A. Self-inhibition is unaffected by the L-type Ca^{2+} channel antagonist (nifedipine) or T- or R-type Ca^{2+} channel antagonists (50 μM Cd^{2+}) but is markedly attenuated by the P/Q- and N-type antagonist ω-conotoxin MVIIC (Isaacson, J. S. and Strowbridge, B. W., 1998). Self-inhibition is reduced by $GABA_B$ receptor agonists, presumably by reducing HVA currents in GCs (Isaacson, J. S. and Vitten, H., 2003). It is also reduced by mGluR antagonists (Heinbockel, T. *et al.*, 2007).

4.37.6.4.2 Lateral inhibition

Stimulation of one mitral cell in the presence of TTX results in a dendrodendritically mediated mitral-granule-mitral cell IPSPs/IPSCs, that is, feedforward or lateral inhibition (Isaacson, J. S. and Strowbridge, B. W., 1998; Urban, N. N. and Sakmann, B., 2002). Like self-inhibition, lateral inhibition in Mg^{2+}-free conditions is completely abolished by NMDA receptor antagonists; in normal extracellular media, AMPA receptors seem to play a more important role when the lateral inhibition is evoked by weaker stimulation (Isaacson, J. S. and Strowbridge, B. W., 1998; Schoppa, N. E. *et al.*, 1998). The spatial extent of lateral inhibition among mitral cells has been reported to be greater than that for tufted cells. Tufted cell lateral inhibition is limited to several glomerular widths (<400 μm) as opposed to 750 μm for mitral cells (Christie, J. M. *et al.*, 2001). The weaker lateral inhibition of tufted cells could merely be due to the fact that their lateral dendrites are relatively short (Mori, K. *et al.*, 1983; Orona, E. *et al.*, 1984). The I_A current strongly regulates the duration of lateral inhibition and the role of AMPA receptors. 4-AP reduces the duration of lateral inhibition and increases the contribution of AMPA receptors. As noted above, 4-AP blocks I_A, which normally occludes or counters the brief AMPA receptor-mediated depolarization and spiking in GCs. I_A blockade disinhibits the AMPA receptor-mediated synaptic component, reduces the latency of evoked spikes, and therefore leads to more rapid and synchronous GABA release from GCs (Schoppa, N. E. and Westbrook, G. L., 1999). Consequently, 4-AP reduces the contribution of the slow kinetics of the NMDA receptor-mediated synaptic component to GC GABA release. The results were somewhat different for self-inhibition, in which the amplitude of early IPSC component was markedly increased, as was the total duration of the IPSC. Blockade of SK currents in mitral cells enhances lateral inhibition (Maher, B. J. and Westbrook, G. L., 2005).

4.37.6.4.3 Role of Ca^{2+} influx through *N*-methyl D-aspartate receptors and voltage-dependent Ca^{2+} channels

Later studies demonstrated that Ca^{2+} influx through the NMDA receptor can directly trigger GABA release from GCs (Halabisky, B. *et al.*, 2000; Chen, W. R. *et al.*, 2000; Isaacson, J. S., 2001). Thus, NMDA applied focally into the EPL in the presence of the HVA Ca^{2+} channel blocker, Cd^{2+}, elicited IPSCs in mitral cells. Similar results were obtained in Mg^{2+}-free conditions when flash photolysis was used to increase intracellular Ca^{2+} in the mitral cell (Chen, W. R. *et al.*, 2000; Isaacson, J. S., 2001); the photolysis-induced IPSC could be blocked by NMDA receptor antagonists or Cd^{2+} (Chen, W. R. *et al.*, 2000; Isaacson, J. S., 2001). The NMDA-evoked IPSC did not depend on Ca^{2+} release from internal stores as it was unaffected by thapsigargin (Halabisky, B. *et al.*, 2000; Chen, W. R. *et al.*, 2000). However, IPSCs elicited by NMDA or KCl

application in the GCL were blocked by Cd^{2+} (Halabisky, B. *et al.*, 2000). These findings suggest that Ca^{2+} influx via NMDA receptors near dendrodendritic synapses, presumably on GC spines, is directly coupled to GABA release. However, depolarization at more remote sites (GC somata/proximal dendrites) induces Ca^{2+} influx via HVA Ca^{2+} channels.

4.37.6.4.4 Local vs. global modes of dendrodendritic inhibition

Current views are that weak stimulation producing small synaptic responses in GCs, and thus Ca^{2+} influx into isolated GCs spines, triggers GABA release and inhibition of mitral cell dendrites that are synaptically coupled to those spines. Such inhibition would tend to be spatially localized. Both NMDA receptors and voltage-dependent Ca^{2+} channels can provide the Ca^{2+} influx necessary for GABA release from spines. By contrast, stronger levels of mitral/tufted cell input that generate actively propagating Na^{+} spikes would produce more global or widespread inhibition of mitral/tufted cells (Chen, W. R. *et al.*, 2000; Egger, V. *et al.*, 2003). As noted above, sufficiently large EPSPs subthreshold for Na^{+} spikes can trigger an all-or-none LTS that propagates throughout the GC dendrites (Egger, V. *et al.*, 2005). Thus, the LTS is an additional candidate for global lateral inhibition.

4.37.6.4.5 Temporal modulation of dendrodendritic inhibition

In slices, paired-pulse mitral cell stimulation experiments show that self-inhibition elicited by the second pulse was markedly reduced and recovered with a time constant of ~6 s (Dietz, S. B. and Murthy, V. N., 2005). This finding may, in part, account for the decrement in GABAergic synaptic input to mitral cells across respiratory cycles during odor stimulation (Cang, J. and Isaacson, J. S., 2003). The observation that GC odor responses subside across sniffs may also lead to reduced dendrodendritic inhibition during respiration. Thus, the strength of dendrodendritic inhibition is likely to be temporally modulated with respect to respiration. Other studies indicate that higher frequency local γ-oscillatory activity generated by mitral cell–GC interactions may also modulate GABAergic inhibition. Local γ-frequency stimulation in the GCL or ELP can facilitate mitral cell feedback and lateral inhibition by relieving the Mg^{2+} block of NMDA receptors on GCs (Halabisky, B. and Strowbridge, B. W., 2003).

4.37.7 Neurophysiology of New, Adult-Born Neurons

The deepest layer in the MOB is the subependymal layer (also called subventricular zone), which is a cell-poor region lining the ventricle (if present) in adults. Most MOB interneurons originate postnatally from progenitor cells within this layer (Hinds, J. W., 1968; Altman, J., 1969; Bayer, S. A., 1983). In adults, interneurons (primarily GCs and PG cells) are continually generated from these progenitor cells, and their offspring generated en route migrates to the MOB within the rostral migratory stream (RMS; Luskin, M. B., 1993; Lois, C. and Alvarez-Buylla, A., 1994; Smith, C. and Lushkin, M. B., 1998; Wichterle, H. *et al.*, 2001). Two subsets of new interneurons have been identified, which express either TH, which is required for DA synthesis, or Ca^{2+} calmodulin-dependent protein kinase IV during migration (Baker, H. *et al.*, 2001). Both the progenitors and new interneurons express functional $GABA_A$ receptors. Electrophysiological studies indicate that the new interneurons subsequently express functional AMPA receptors, then NMDA receptors, before they exhibit spiking activity, responses to ON stimulation, and spontaneous glutamatergic EPSCs (Belluzzi, O. *et al.*, 2003; Carleton, A. *et al.*, 2003). These electrophysiological studies provide evidence that the new interneurons become functionally integrated into the MOB circuitry. Neural cell-adhesion protein-deficient mice, which exhibit defective migration of new interneurons into the GCL and a reduced MOB size, have been shown to exhibit impaired odor discrimination (Gheusi, G. *et al.*, 2000). Although threshold detection and short-term odor memory were normal in these mice, in normal mice both olfactory memory and survival of the new interneurons were improved following rearing in an odor-enriched environment (Rochefort, C. *et al.*, 2002). Thus, the neurons of the subependymal layer and RMS appear to be important both to MOB development and to certain olfactory functions during adulthood.

4.37.8 Neurophysiology of Primary Olfactory Cortical Inputs to Main Olfactory Bulb

Extrinsic afferent input to MOB, also referred to as centrifugal fibers, can be subdivided into two

classes: (1) inputs arising from nonolfactory, so-called neuromodulatory transmitter systems including ACh, norepinephrine (NE), and 5-HT (these neuromodulatory inputs are discussed below in Neurophysiology of Neuromodulatory Inputs to Main Olfactory Bulb), and (2) feedback inputs arising from olfactory-related structures, in particular those arising from POC. Feedback projections to MOB from POC arises predominantly from glutamatergic, pyramidal neurons in layers II and III of piriform cortex, as well as other POC structures (for review, see Ennis, M. *et al.*, 2007). These projections massively target GCs, where they form asymmetrical synapses on the cell bodies, basal dendrites, and spines of GCs (Price, J. L. and Powell, T. P. S., 1970a). Activation of these feedback projections produces a negative field potential recorded in the GCL (Walsh, R. R., 1959; Nakashima, M. *et al.*, 1978), as expected if excitatory currents are flowing into GCs. Similar stimulation elicits IPSPs in mitral cells (Yamamoto, C. *et al.*, 1963; Nicoll, R. A., 1971; Mori, K. and Takagi, S. F., 1978), due to excitation of GCs, followed by GABA release onto mitral cells, that is, dendrodendritic inhibition (Halász, N. and Shepherd, G. M., 1983). The transmitter of these feedback projections to GCs is glutamate. Activation of POC input to MOB excites GCs as measured by voltage-sensitive dye and field potential recordings *in vitro*. This excitation is mediated by glutamate acting at both AMPA and NMDA receptors (Laaris, N. *et al.*, 2007). A major function of these projections is to provide an inhibitory regulation of the firing rate and excitability state of mitral/tufted cells. Activation of these inputs modifies (inhibits) odor responses in MOB (Kerr, D. I. B. and Hagbarth, K. E., 1955).

4.37.9 Oscillations and Synchrony in Main Olfactory Bulb

4.37.9.1 Oscillations

Oscillations and synchronous activity are characteristic features of spontaneous and odor-driven activity in the MOB and other olfactory structures. A detailed consideration of oscillations in the MOB is beyond the scope of the present review and has recently been reviewed elsewhere (Lledo, P. M. *et al.*, 2005; Gelperin, A., 2006; Kepecs, A. *et al.*, 2006). Prominent oscillatory activity is present in MOB field potentials, which primarily reflect synchronized subthreshold membrane potentials arising from large neuronal populations, or in membrane potential or spike activity of individual MOB neurons. Sensory input to the olfactory system occurs as a result of respiration which by its very nature is cyclical or rhythmical. Relatively low-frequency oscillations synchronized to respiration, in the presence and absence of odors, occur in the theta band (2–12 Hz). Higher frequency oscillations, superimposed on the theta, occur in the beta (15–40 Hz) and gamma (30–80 Hz) bands. Beta frequency oscillations are relatively poorly understood, but have recently been discussed elsewhere (Neville, K. R. and Haberly, L. B., 2003; Martin, C. *et al.*, 2004; Fletcher, M. L. *et al.*, 2005). Lower frequency oscillatory (0.1–0.03 Hz) and synchronous activity has been observed in MOB slices under certain conditions (Puopolo, M. and Belluzzi, O., 2001).

4.37.9.1.1 Theta rhythm

In the MOB, 2 to 12 Hz oscillations are referred to as theta principally because they occupy a highly overlapping frequency band with hippocampal theta oscillations (Kay, L. M. and Laurent, G., 1999; Kay, L. M., 2003; 2005). As noted above, theta frequency oscillations are driven by, and thus synchronized or phase-locked with, respiration. Therefore, the specific theta frequency varies with the sniffing frequency (i.e., the pattern of airflow across the nasal epithelium) and includes components related to low-frequency (1–3 Hz) passive sniffing as well as a higher frequency component (5–12 Hz) characteristic of active investigative sniffing (Adrian, E. D., 1950; Welker, W. I., 1964; Macrides, F. *et al.*, 1982; Eeckman, F. H. and Freeman, W. J., 1990; Kay, L. M. and Laurent, G., 1999; Kay, L. M., 2003). As noted earlier, mitral cell subthreshold membrane potential oscillations and/or spike activity is synchronized with certain phases of the respiratory cycle. Manipulations that impair or disrupt respiratory-driven input to the MOB disrupts mitral cell activity and decouples it from the respiratory cycle (Philpot, B. D. *et al.*, 1997). Thus, theta oscillations appear to be driven by the pattern of respiratory-driven input to MOB. However, intrinsic membrane and synaptic properties enhance the ability of some MOB neurons to entrain or synchronize with rhythmical respiratory-driven activity. For example, ET cells in MOB slices intrinsically generate spike bursts at frequencies ranging from ~1 to 8 Hz, and readily entrain to patterned sensory input over this same range. Thus, the properties of these

cells may allow them to discharge in synchrony with the respiratory cycle.

4.37.9.1.2 Gamma rhythm

Gamma oscillations arise during odorant or direct ON stimulation and appear to be generated intrinsically in the MOB. Thus, they persist when centrifugal input to the bulb is severed or impaired (Gray, C. M. and Skinner, J. E., 1988; Neville, K. R. and Haberly, L. B., 2003). As with theta oscillations, odor- or ON-evoked gamma oscillations are apparent in the EEG, MOB field potentials, and subthreshold membrane potential and spiking activity of mitral cells (Adrian, E. D., 1950; Eeckman, F. H. and Freeman, W. J., 1990; Kay, L. M. and Freeman, W. J., 1998; Kashiwadani, H. *et al.*, 1999; Debarbieux, F. *et al.*, 2003; Friedman, D. and Strowbridge, B. W., 2003; Neville, K. R. and Haberly, L. B., 2003; Lagier, S. *et al.*, 2004; Martin, C. *et al.*, 2004; Fletcher, M. L. *et al.*, 2005). Current source-density analyses indicate that the gamma oscillations in MOB field potentials primarily reflect synaptic currents flowing in GCs (Neville, K. R. and Haberly, L. B., 2003). Multisite recordings demonstrated that the phase of gamma oscillation may vary in different parts of the MOB, especially at low odor concentrations. Gamma oscillations are thought to arise primarily as a result of rhythmic or reverbatory interactions between mitral/tufted cells and inhibitory interneurons, chiefly GCs (Friedman, D. and Strowbridge, B. W., 2003; Neville, K. R. and Haberly, L. B., 2003; Lagier, S. *et al.*, 2004). Mitral cell activity is synchronized with γ-frequency MOB field potentials and also with GABAergic synaptic input (Lagier, S. *et al.*, 2004). The duration of mitral cell to GC synaptic input occurs over a time course of approximately one-half cycle of the gamma oscillation. Gamma oscillatory activity in mitral cells is suppressed or attenuated by glutamate receptor antagonists (decreasing mitral/tufted cell excitation of GCs) or by $GABA_A$ receptor antagonists (blocking GC-mediated inhibition of mitral/tufted cells) (Friedman, D. and Strowbridge, B. W., 2003; Lagier, S. *et al.*, 2004). In $GABA_A$ $\beta 3$ receptor subunit-deficient mice, functional expression of GC $GABA_A$ receptors was almost eliminated (Nusser *et al.*, 2001). In these mice amplitudes of mitral/tufted cell miniature IPSPs, theta-frequency oscillations, and γ-frequency oscillations were increased, and discrimination of closely related mixtures of alcohols after training was poor relative to normal mice. Gamma oscillations also appear to involve electrical synapses as they are suppressed by gap junction inhibitors (Friedman, D. and Strowbridge, B. W., 2003). Consistent with this, gamma oscillations are disrupted in connexin36-knockout mice (Hormuzdi, S. G. *et al.*, 2001). Intrinsic membrane properties of mitral cells may facilitate gamma oscillatory activity and spiking. When near spike threshold, mitral cells exhibit intrinsically generated subthreshold membrane potential oscillations in the γ-frequency range (Chen, W. R. and Shepherd, G. M., 1997; Desmaisons, D. *et al.*, 1999).

4.37.9.2 Synchrony

Synchrony can be defined as a temporal coincidence between two or more events that have a low probability of occurring by random or chance. Neurons involved in the detection and processing of odors show temporally correlated or synchronized activity, a feature that is expected to have functional relevance for understanding the population code in the olfactory system (Laurent, G., 2002).

4.37.9.2.1 Synchrony among JG cells

JG neurons associated with the same glomerulus exhibit highly synchronous spontaneous activity. Simultaneous recordings of ET–PG or ET–SA cell pairs demonstrated that spikes in ET cells drive synchronous activity in PG and SA cells, but only if the dendrites of both cells ramified in the same glomerulus (Figure 14) (Hayar, A. *et al.*, 2004b). This intraglomerular synchronous activity is driven by glutamatergic input from ET cells to PG/SA cells and is abolished by AMPA receptor antagonists. Similar studies revealed that spontaneous spikes and subthreshold membrane potential activity (i.e., EPSPs, IPSPs) among ET cells of the same glomerulus is highly synchronous (Figure 14) (Hayar, A. *et al.*, 2004b; 2005). Interestingly, the frequency of spontaneous inhibitory input to ET cells, which primarily originates from PG cells, occurs around 50 Hz (γ frequency) and is similar to the frequency of ON-evoked γ-oscillations in mitral cells (mean 45 Hz, Lagier, S. *et al.*, 2004). Although spontaneous synaptic input can synchronize ET cells, synchrony among these cells persists when ionotropic glutamate and GABA receptors are blocked (Hayar, A. *et al.*, 2004b; 2005). Additional electrophysiological results demonstrated that ET cells of the same glomerulus are electrotonically coupled via gap junctions with a relatively small conductance (0.1 nS). Spontaneous synchrony among ET cells is

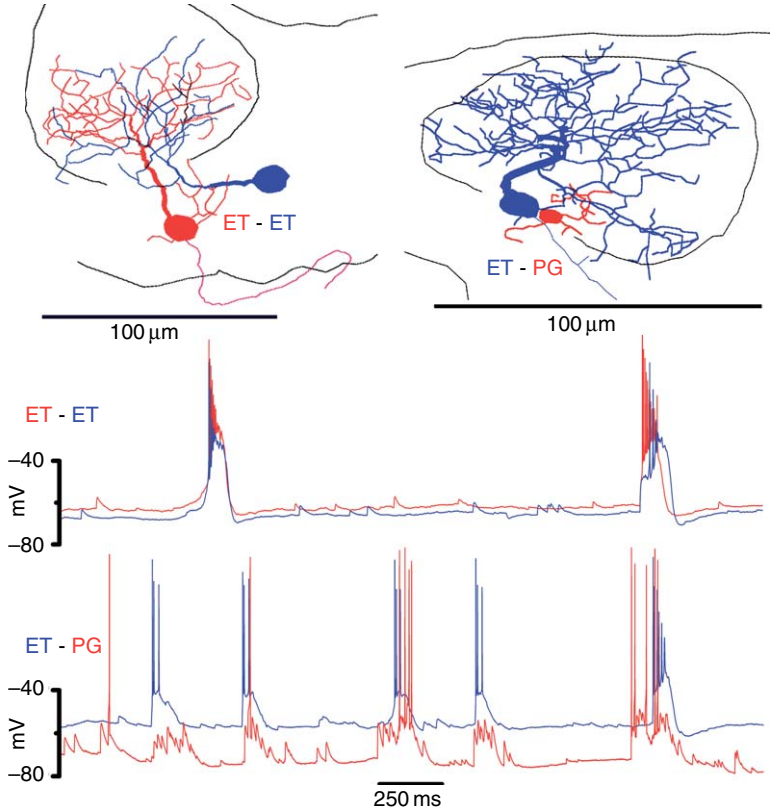

Figure 14 Synchronous activity among juxtaglomerular (JG) cells associated with the same glomerulus. Upper panel shows reconstructions of the recorded cells (left, two external tufted (ET) cells; right, an ET cell and a periglomerular (PG) cell). Middle panel: Dual whole-cell current clamp recording from two ET cells (red and blue traces, respectively) showing correlation of spike bursts and membrane potentials. Lower panel: Dual whole-cell current clamp recordings show that EPSP bursts and spikes in a PG cell (red trace) are synchronous with spike bursts in an ET cell (blue trace).

abolished by the gap junction blocker carbenoxolone (Hayar, A. *et al.*, 2005). These results are consistent with anatomical evidence for gap junctions between mitral/tufted cell apical dendrites (See Section 4.37.9.2.2). Unlike mitral cells, which exhibit a narrow window of spike-to-spike correlation (see below; Schoppa, N. E. and Westbrook, G. L., 2002), ET cells exhibit a broader window of burst-to-burst correlation. The narrow window of correlation among mitral cells is due to the fact that mitral cell spikes induced fast EPSPs in other mitral cells (Schoppa, N. E. and Westbrook, G. L., 2002). In contrast, ET cells seem to communicate mainly via slow inward currents produced by gap junctions with relatively low conductance. Therefore, one potential function of gap junctions in ET cells is to filter fast spiking activity and propagate slow membrane potential oscillations, which are driven mainly by persistent Na^+ current (Hayar, A. *et al.*, 2004a).

4.37.9.2.2 Synchrony among mitral cells

Synchronous activity in the mammalian MOB occurs among mitral cells that send an apical dendrite to receive input from a single glomerulus. By using simultaneous recordings from pairs of mitral cells, it has been shown that pairs with apical dendrites in the same glomerulus display highly synchronized synaptic and/or spike activity, whereas pairs associated with different glomeruli do not. As reviewed earlier, mitral cells associated with the same glomerulus exhibit synchronous AMPA receptor-mediated LLDs that spontaneously occur at a frequency of ~1 Hz (Carlson, G. C. *et al.*, 2000). LLDs (Figure 7) are generated by network activity in the glomeruli and could be elicited by ON or antidromic stimulation, but never by depolarization of single mitral cells. Subsequent studies demonstrated that slow (2 Hz) oscillations and spikes elicited by single ON shocks or NMDA application were synchronous among mitral cells of the same glomerulus; cells

associated with distant glomeruli did not exhibit synchrony, while those associated with adjacent glomeruli exhibited temporally correlated but not synchronous oscillations (Schoppa, N. E. and Westbrook, G. L., 2001; 2002). The synchronous activity among mitral cells was abolished by AMPA receptor antagonists and dampened by mGluR antagonists (Schoppa, N. E. and Westbrook, G. L., 2001; 2002). These and later studies indicated that mitral cell apical dendrites in the same glomerulus exhibit electrotonic coupling (Schoppa, N. E. and Westbrook, G. L., 2002; Christie, J. M. *et al.*, 2005). In mouse MOB slices, current injections into one cell elicited correlated spikes in a second mitral cell if the dendrites extended into the same glomerulus. Such synchrony, however, was absent in slices from connexin36-knockout mice (Christie, J. M. *et al.*, 2005). Connexins are a member of gap junction proteins involved in electrical signaling between cells. The preceding finding is consistent with the presence of high levels of connexin36 in MOB neurons, and specifically in mitral/tufted dendrites (Condorelli, D. F. *et al.*, 1998; 2000; Belluardo, N. *et al.*, 2000; Rash, J. E. *et al.*, 2000; Teubner, B. *et al.*, 2000; Zhang, C. and Restrepo, D., 2003; Christie, J. M. *et al.*, 2005). Other studies have also reported gap junctions in, or between, mitral/tufted cell dendrites (Paternostro, M. A. *et al.*, 1995; Miragall, F. *et al.*, 1996; Kosaka, T. and Kosaka, K., 2003; 2004). In slices from wildtype, but not connexin36-knockout mice, a spike elicited in one mitral cell evoked an AMPA receptor-mediated potential (D_{AMPA}) in the second mitral cell (Christie, J. M. *et al.*, 2005). Correlated spiking in connexin36-knockout mice could be reinstated by boosting glutamate levels with uptake inhibitors. Taken together, these findings indicate that electrical coupling is necessary to drive D_{AMPA}, which in turn, drives correlated spiking among mitral cells. Thus, the apical dendrites of mitral cells generate a unique form of electrochemical transmission. The dependence of correlated spiking on AMPA receptors is a distinct feature of mitral–mitral cell synchrony.

GABAergic inhibition is also thought to play an important role in synchronizing mitral cell activity. As noted earlier, γ-frequency oscillation and spiking is a prominent feature of mitral cell odor-evoked activity. Spontaneous synchronous IPSPs can reset the phase of subthreshold membrane oscillations and synchronize the firing of multiple mitral cells (Desmaisons, D. *et al.*, 1999). Correlated IPSPs might also contribute to the odor-elicited high-frequency oscillations in the olfactory bulb of adult rats (Fletcher, M. L. *et al.*, 2005). The frequency of ON-evoked local field potential oscillations (mean 45 Hz, Lagier, S. *et al.*, 2004) recorded in the MCL is attributed to rhythmic dendrodendritic granule to mitral cell inhibition. Unlike glomerular mechanisms, GABAergic inhibition appears to synchronize mitral cells associated with different glomeruli. Mitral cell associated with different glomeruli can be synchronized by rhythmic stimulation of the ON at theta frequencies (Schoppa, N. E., 2006). Such synchrony does not depend upon electrotonic coupling, but appears to be driven by synchronous IPSPs from GCs, such that synchronous spikes in mitral cells occur during the recovery from the synchronous IPSP. One possible function of spike synchrony among mitral cells of different odorant receptor specificities is to provide a mechanism for downstream cortical neurons to decode information about different odorant receptors (Schoppa, N. E., 2006). As would be required by such a mechanism, labeling studies suggest that each pyramidal cell in the anterior piriform cortex receives anatomical connections from mitral cells with different odorant receptor specificities (Zou, Z. *et al.*, 2001). Assuming that pyramidal cells in the olfactory cortex have synaptic integration windows comparable to other pyramidal neurons (e.g., $\sim$7 ms), synchrony among mitral cells would promote the summation of EPSPs and the likelihood that cortical neurons fire action potentials in response to input from activated mitral cells of different odorant receptor specificities.

4.37.9.3 Oscillations, Synchrony and Odor Coding

Temporal firing patterns, including rhythmic oscillations and neuronal synchronization, are thought to be important in sensory information processing (Alonso, J. M. *et al.*, 1996; Konig, P. *et al.*, 1996; Roy, S. A. and Alloway, K. D., 2001) including odor coding (for review, see Friedrich, R. W., 2002). Rhythmic activity and synchrony are thought to coordinate intra- and interstructural communication. Olfactory information is thought to be encoded, at least in part, by network oscillations (Wehr, M. and Laurent, G., 1996; Kauer, J. S., 1998; Kay, L. M. and Laurent, G., 1999). In the first stage of olfactory processing, network interactions within each glomerulus act to synchronize the discharge of mitral cells associated with that glomerulus to the theta pattern of rhythmical sensory input. By temporally binding the discharge of mitral cells, such

synchrony would maximize the transfer of sensory input onto the output neurons. This, in turn, would facilitate faithful transfer of glomerular sensory input to higher order olfactory structures (i.e., POC). In other words, temporal summation of EPSPs produced by synchronous spikes from the glomerular ensemble of mitral/tufted cells would increase the likelihood of spike initiation in postsynaptic POC neurons. Glomerular synchrony may be a particularly important amplification mechanism when odor concentrations are insufficient to activate all mitral cells of a particular glomerulus. Odors typically activate multiple glomeruli, but the mechanism that drives the sensory input (respiration) is common to all glomeruli. Does this imply that oscillations and synchrony should be phase-locked across responsive glomeruli? This does not seem to be the case as the widespread distribution of ORNs and their odorant response kinetics produce temporal variations in odor response properties in different glomeruli. Thus, different glomeruli activated by the same odorant exhibit temporally distinct response profiles (Spors, H. *et al.*, 2006). It is likely, therefore, that at least initially there will be temporal differences in the phase of oscillatory neuronal activity and synchrony among neurons in different responsive glomeruli. In addition, both glomerular odor activity patterns and discharge of mitral cells change within and across sniffs (Friedrich, R. W., 2002; Spors, H. *et al.*, 2006), and as noted above, the phase of gamma oscillations may not always be uniform throughout the MOB. Neurons in POC appear to receive convergent input from multiple glomeruli (Zou, Z. *et al.*, 2001; Illig, K. R. and Haberly, L. B., 2003). Temporal variations in activity patterns from different glomeruli, via mitral/tufted cells, may be an important element in odor recognition and discrimination.

4.37.10 Neurophysiology of Neuromodulatory Inputs to Main Olfactory Bulb

MOB receives extrinsic inputs from cholinergic, noradrenergic, and serotonergic groups in the basal forebrain and brainstem. As these inputs innervate neurons in multiple layers of MOB, and therefore modulate multiple neuronal subtypes, their physiological effects are collectively reviewed here.

4.37.10.1 Cholinergic Inputs to MOB

In the mouse, about 3.5% of all neurons that project to the bulb originate in the nucleus of the horizontal limb of the diagonal band (NDB); far fewer originate in the vertical limb of DB (Carson, K. A., 1984; Shipley, M. T., and Adamek, G. D., 1984). At least two distinct transmitter-specific populations of NDB neurons project to the MOB (Zaborszky, L., *et al.*, 1986). About 20% of the NDB neurons that project to the bulb are cholinergic; most of these cells are concentrated in the rostromedial portion of the horizontal limb of NDB. Many NDB–MOB projection neurons are GABAergic and occur mainly in the caudo-lateral aspect of NDB (Zaborszky, L., *et al.*, 1986). Choline acetyltransferase, the biosynthetic enzyme for ACh synthesis, is located in axons distributed across most layers of the MOB, except the ONL; cholinergic fibers are especially heavy in the GL and IPL (Ennis, M. *et al.*, 2007). As reviewed elsewhere, muscarinic and nicotinic receptors are found in most layers of MOB (Ennis, M. *et al.*, 2007).

Electrical activation of NBD has been reported to depress (Nickell, W. T. and Shipley, M. T., 1988) or to increase (Kunze, W. A. A. *et al.*, 1991; 1992) mitral cell activity indirectly via primary effects on GABAergic GCs. NDB stimulation also reduced the field potential in the MOB caused by stimulation of the anterior commissure (Nickell, W. T. and Shipley, M. T., 1993), an effect mediated by presynaptic inhibition of anterior commissure terminals via muscarinic receptors. One interpretation of these results is that cholinergic input to MOB may function to modulate interhemispheric transmission of olfactory information. In this regard, it is noteworthy that anterior commissural fibers are required for access and recall of olfactory memories between the two hemispheres. Infusion of ACh into MOB was reported to reduce paired-pulse depression of LOT-evoked field potentials recorded in the GCL. This effect was attributed to muscarinic receptor-mediated inhibition of GABA release from GCs (Elaagouby, A. *et al.*, 1991). In slice preparations, nicotinic but not muscarinic receptor agonists directly excited mitral cells, and this effect appeared to be due to an inward current with a reversal potential of -5 to $+10$ mV (Castillo, P. E. *et al.*, 1999). In slices, muscarinic receptor agonists inhibited GCs (Castillo, P. E. *et al.*, 1999), and paradoxically, also appeared to increase GABA release from these cells. The same study reported that in the GL only bipolar PG cells were sensitive to nicotine (Castillo, P. E.

et al., 1999). The morphological identity of these cells is unclear. Behaviorally, muscarinic receptor antagonists impair discrimination among closely related odors (Fletcher, M. L. and Wilson, D. A., 2002).

4.37.10.2 Noradrenergic Input to MOB

A significant modulatory input to the bulb is from the pontine nucleus locus coeruleus (LC). In the rat, all LC neurons contain the neurotransmitter, NE; LC contains the largest population of NE neurons in the brain. It has been estimated that up to 40% of LC neurons (400–600 of a total of 1600 LC neurons) project to the bulb in the rat (Shipley, M. T. *et al.*, 1985). A subset of LC neurons projecting to MOB contain NPY (Bouna, S. *et al.*, 1994). LC axons project mainly to the subglomerular layers of the bulb, particularly in the IPL and GCL (McLean, J. H., *et al.*, 1989). The EPL and MCL are moderately innervated, while the GL is nearly devoid of NE input. NE receptors occur in multiple layers of the MOB and are expressed by multiple cell types, in general consistent with the pattern of NE fiber innervation (for review, see Ennis, M. *et al.*, 2007).

While NE clearly plays significant roles in olfactory function, the effects of NE at the cellular and network levels are somewhat discrepant. For example, LC stimulation was reported to have no effect on LOT-evoked field potentials recorded in the GCL (Perez, H. *et al.*, 1987). A subsequent study reported that LC stimulation initially decreased and then subsequently increased paired-pulse depression of GC field potential responses to LOT stimulation (Okutani, F. *et al.*, 1998). These effects were attributed to activation of β receptors. Another field potential study reported that NE infusion into MOB, acting at $\alpha 1$ receptors, increased the depolarization of GC dendrites elicited by LOT stimulation. Mitral cell responses to antidromic shocks were not affected, suggesting that NE excites GCs (Mouly, A. M. *et al.*, 1995). In neonatal animals, β receptor stimulation in MOB decreased LOT-evoked, paired-pulse inhibition of GC field potentials (Wilson, D. A. and Leon, M. 1988). It is unclear if this was mediated by presynaptic inhibition of transmitter release from MCs and/or increased excitability of GCs.

Cellular recording studies are also somewhat discrepant. In the rabbit and cat, Salmoiraghi *et al.* (1964) and McLennan (1971) found that iontophoretically applied NE inhibited mitral cells. This effect was blocked by the $GABA_A$ receptor antagonist, bicuculline. In the isolated turtle bulb (Jahr and Nicoll, 1982), mitral cell spike rate increased and IPSPs decreased following both application of NE. In dissociated MOB cultures, NE decreased mitral to granule dendrodendritic synaptic transmission by acting presynaptically at $\alpha 2$ receptors to decrease Ca^{2+} currents in both granule and mitral cells (Trombley, P. Q., 1992; Trombley, P. Q. and Shepherd, G. M., 1992).

NE release or NE agonists have more consistent effects on ON-evoked responses in mitral cells. NE release, evoked by selective chemical activation of LC *in vivo*, enhanced the response of mitral cells in response to weak (i.e. perithreshold) but not strong (i.e. suprathreshold) stimulation of the olfactory epithelium (Jiang, M. R. *et al.*, 1996). Interestingly, NE release from LC axon terminals is facilitated and suppressed by activation of presynaptic nicotinic and muscarinic cholinergic receptors, respectively (El-Etri, M. M. *et al.*, 1999). Consistent with these *in vivo* findings, application of NE or $\alpha 1$ receptor agonists, but not $\alpha 2$ or β-receptor agonists, selectively increased mitral cell responses to perithreshold intensity ON stimulation in rat MOB slices (Figure 15) (Ciombor, K. J. *et al.*, 1999). Noradrenergic agonists were without effect on ON-evoked field potentials recorded in the GL, or on ON-evoked postsynaptic currents in mitral cells (Hayar, A. *et al.*, 2001). This suggests that NE-evoked modulation of ON-evoked mitral cell spiking is mediated by postsynaptic actions on bulb neurons. In voltage-clamp recordings, NE or $\alpha 1$ agonists directly evoked an inward current in mitral cells that appeared to be due to closure of K^+ channels (Figure 16). In current clamp recordings from bistable mitral cells, $\alpha 1$ agonists shifted the membrane potential from the downstate (-52 mV) toward the upstate (-40 mV) and significantly increased spike generation in response to perithreshold ON input. Taken together, these findings suggest that NE release directly alters mitral cell excitability in a manner that could increase their sensitivity to weak ON input, perhaps to improve the detection of weak odorants.

NE inputs to the bulb are critical to olfactory function. Olfactory cues increase the discharge of LC neurons in behaving animals (Aston-Jones, G. and Bloom, F. E., 1981) and trigger rapid increases in NE levels in the MOB (Chanse, N. T. and Kopin, I. J., 1968; Rosser, A. E. and Keverne, E. B., 1985; Brennan, P. *et al.*, 1990). LC projections to the main and accessory olfactory bulb are pivotal to the formation of specific olfactory memories, pheromonal

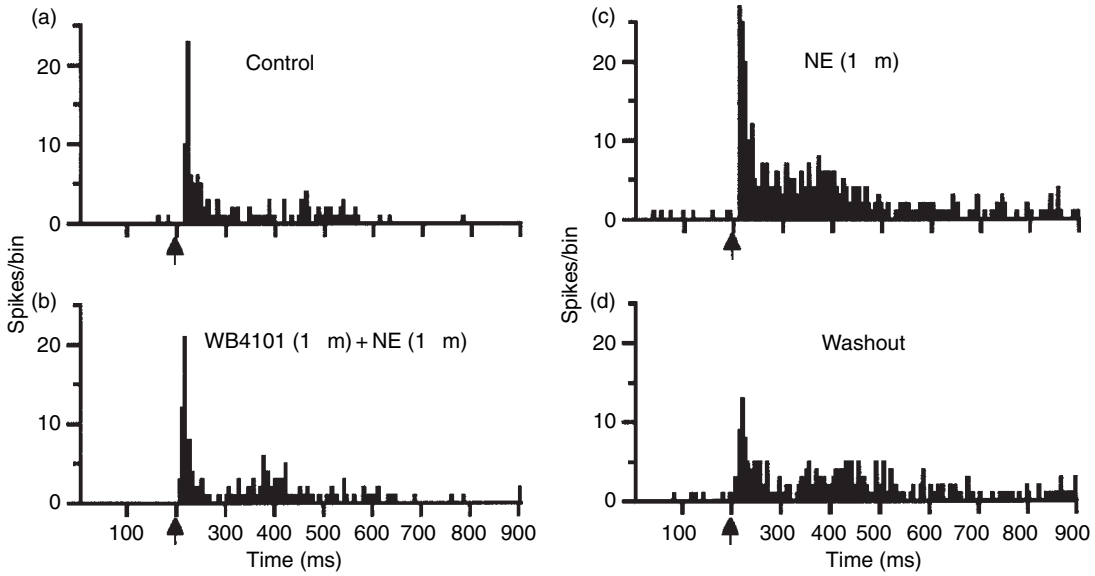

Figure 15 The α1 receptor antagonist WB-4101 prevents norepinephrine (NE)-induced facilitation of mitral cell excitatory responses to perithreshold intensity olfactory nerve (ON) stimulation. (a–d) Peri-stimulus time histograms (PSTHs) showing responses of a mitral cell to perithreshold intensity ON shocks (12 μA, at arrows). (a and b) In the presence of WB-4101 (1 μM), superfusion of NE (1 μM) did not alter (103% of control) the early excitation elicited by ON stimulation. (c) After washout of WB-4101, NE substantially increased (184% of control) the early excitatory response component. (d) The facilitation of the early excitation recovered by 53 min after washout of NE. All PSTHs were generated for 50 consecutive ON shocks. Reprinted from Ciombor, K. J., Ennis, M., and Shipley, M. T. 1999. Norepinephrine increases rat mitral cell excitatory responses to weak olfactory nerve input via alpha-1 receptors *in vitro*. Neuroscience 90, 595–606, with permission from Elsevier, Ltd.

regulation of pregnancy and post-partum maternal behavior (Kaba, H. and Keverne, E. B., 1988; Brennan, P. *et al.*, 1990; Kendrick, K. M. *et al.*, 1992). NE plays an important role in the so-called Bruce effect in mice: when impregnated female mice are exposed to the odor of a strange male, they abort; if exposed to the odor of the impregnating male, they do not abort (Kaba, H. and Keverne, E. B., 1989). Systemic administration of adrenergic receptor antagonists or 6-OHDA lesions, selectively destroying only the NE inputs to the MOB, causes the female to abort when presented with the odor of the impregnating male (Rosser, A. E. and Keverne, E. B., 1985; Kaba, H. and Keverne, E. B., 1988; Brennan, P. *et al.*, 1990). Finally, NE has been shown to play a critical role in olfactory learning in young animals. In neonatal rats, NE release via tactile stimulation leads to a preference for an odor associatively paired with this stimulation (Sullivan, R. M. *et al.*, 1989). The conditioned preference is associated with odor-specific metabolic changes in the bulb (Coopersmith, R. and Leon, M., 1984). Following the conditioning, there is an increased inhibition of mitral cells by the odor (Sullivan, R. M. *et al.*, 1989). Such conditioning is abolished by eliminating NE input to the bulb or via β-receptor antagonists (Sullivan, R. M. *et al.*, 1989; Wilson, D. A. and Sullivan, R. M., 1991; Sullivan, R. M. *et al.*, 1992; 2000; Moriceau, S. and Sullivan, R. M., 2004). Recent studies from McLean's laboratory demonstrate that this β-receptor-dependent neonatal learning involves activation of intracellular cAMP and cAMP-response element-binding protein (CREP) pathways (Yuan, Q. *et al.*, 2003; McLean, J. H. and Harley, C. W., 2004).

4.37.10.3 Serotonergic (5-HT) Input to MOB

The midbrain dorsal and median raphe provides strong serotonergic inputs to the MOB. In the rat, about 1000 dorsal and 300 median raphe neurons project to the bulb (McLean, J. H. and Shipley, M. T., 1987a; 1987b). 5-HT fibers are present in all layers of MOB, but with varying densities. Input to the GL is especially dense, while the EPL contains very low density. The MCL, IPL, and GCL have a fairly heavy and uniform innervation, but not as dense as that of the GL. Thick serotonergic fibers preferentially innervate the glomeruli of MOB, while

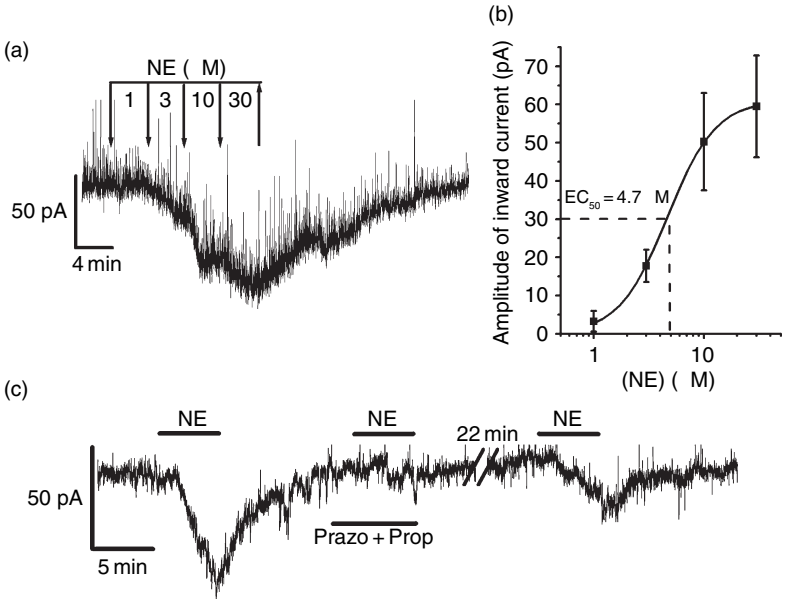

Figure 16 Effect of norepinephrine (NE) in voltage-clamp recordings from mitral cells. (a) Inward currents evoked by NE at different concentrations (1, 3, 10, and 30 μM added cumulatively, 4 min at each concentration). (b) A sigmoidal curve was fitted to the NE concentration–response data obtained from four cells. The holding potential was −60 mV. (c) The response to a second application of NE (30 μM) was blocked in the presence of the alpha 1 receptor antagonist prazosin (Prazo; 1 μM) and the beta receptor antagonist propranolol (Prop; 10 μM). The NE-induced inward current recovered partially after washout of the antagonists (about 30 min). Reprinted from Hayar, A., Heyward, P. M., Heinbockel, T., Shipley, M. T., and Ennis, M. 2001. Direct excitation of mitral cells via activation of alpha1-noradrenergic receptors in rat olfactory bulb slices. J. Neurophysiol. 86, 2173–2182, with permission from The American Physiological Society.

thinner serotonergic axons preferentially innervate inframitral layers (McLean, J. H. and Shipley, M. T., 1987a; 1987b). In neocortex, thick axons arise from the median raphe and thin axons arise from dorsal raphe (McLean, J. H. and Shipley, M. T., 1987a; 1987b), and the same segregation occurs in MOB. In agreement with the 5-HT fiber distribution, 5-HT receptors are localized in most layers of the MOB (for review, see Ennis, M. *et al.*, 2007).

In the GL, it was recently reported that 5-HT depolarized 34% of JG cells *in vitro* via activation of $5HT_{2C}$ receptors (Hardy, A. *et al.*, 2005). The 5-HT-induced depolarization was due to activation of a nonselective cation current with a reversal potential of −44 mV. The heterogeneous electrophysiological properties of 5-HT-responsive JG cells suggested that several types of JG cells could be targeted by 5-HT centrifugal fibers. A subset of mitral cells was also depolarized by 5-HT acting at $5\text{-}HT_{2A}$ receptors. By contrast with these results, another subset of mitral cells was hyperpolarized by 5-HT, an action that was indirectly mediated by GCs as it was blocked by $GABA_A$ receptor antagonists (Hardy, A. *et al.*, 2005). This effect of 5-HT was also thought to be mediated by $5\text{-}HT_{2A}$ receptors. Behavioral studies indicate that lesion of serotonergic fibers reversed conditioned olfactory learning (Morizumi, T. *et al.*, 1994) and also induced glomerular atrophy. Behavioral work on neonates by McLean (McLean, J. H. *et al.*, 1996) showed that 5-HT depletion or $5\text{-}HT_2$ receptor antagonism compromised olfactory learning and that 5-HT release or $5\text{-}HT_2$ receptor activation promoted odor conditioning. 5-HT release also appears to facilitate β receptor-mediated, NE-induced olfactory learning by facilitating cAMP-mediated mechanisms (McLean, J. H. and Harley, C. W., 2004).

Glossary

odorant The physical stimulus that gives rise to the perception of an odor. The same odorant may give rise to different odor percepts, depending on context, expectation, and past experience.

paleocortex An evolutionarily old cortical structure with generally three lamina, as opposed to the six-layered evolutionarily more recent neocortex. Piriform cortex is an example of paleocortex.

perceptual learning An enhancement in fine sensory discrimination based on past experience. Perceptual learning has been demonstrated in most sensory modalities including vision, audition, somatosensation, and olfaction.

thalamocortical system An organization typical of most sensory systems, wherein a thalamic nucleus receives input from the sensory peripheral circuits and transmits this information to the sensory neocortex, Olfaction includes both a nonthalamocortical system of olfactory bulb projections directly to the piriform cortex, and also a thalamocortical system of mediodorsal thalamic nucleus input to the orbitofrontal cortex.

4.38.1 Introduction

Sensory receptors are generally highly analytical. Your retina and photoreceptors pixilate this printed page into tiny points of light within a relatively narrow range of wavelengths. The tips of your fingers have separate receptor populations for rough surfaces and smooth surfaces, and for hot and cold. As noted in earlier chapters, your nose contains several hundred different olfactory receptors responsive to different submolecular features of volatile compounds, huge subsets of which are activated when inhaling chemically rich everyday odors such as cheese or wine. In contrast, sensory cortex is often the epitome of synthetic. In visual sensory cortex, pixilated images get combined with past experience to allow to one see and recognize objects. In somatosensory cortex, smooth gets put together with cold when we run

our finger tips over an ice cube. And in the olfactory sensory cortex, the 655 different volatiles rising over a cup of coffee, so carefully dissected by the olfactory periphery, get merged into the only stimulus capable of getting me out of bed this morning – the single percept, coffee.

This chapter will review our current understanding of the structure and function of olfactory sensory cortex. Olfaction is unique among mammalian sensory systems in that second-order neurons project directly to the primary sensory cortex, without an intervening thalamic relay. However, there is also a thalamocortical olfactory pathway, highly interconnected with primary olfactory cortex and only just beginning to be fully explored. While our understanding of peripheral mechanisms of olfactory coding has grown exponentially in the past decade or two, it is increasingly apparent that to understand olfactory perception we must understand what olfactory sensory cortex does. For example, knowing that there are different opsin proteins in the cones of your retina differentially sensitive to light wavelength is not sufficient to explain the visual perception of a rainbow or an orchid. Similarly, our perception of, and ability to discriminate between, odors depends not only on events happening at the receptor, but very critically on events within sensory cortex. The experience- and context-dependent nature of olfactory perception, in fact, make very clear that knowing which receptors and olfactory bulb glomeruli are activated by a particular stimulus is insufficient to predict the resulting percept. We will review what we currently understand about the contribution of olfactory cortex to odor coding and the mechanisms underlying these contributions.

4.38.1.1 Functions of Sensory Cortex

Sensory cortical circuits have at least three primary functions (see Figure 1). The first is to elaborate upon the representation of afferent input begun by more peripheral structures. This cortical elaboration may occur through processes such as decorrelation of patterned afferent activity to enhance discrimination of similar patterns, convergence and synthesis of diverse inputs to promote emergence of wholistic

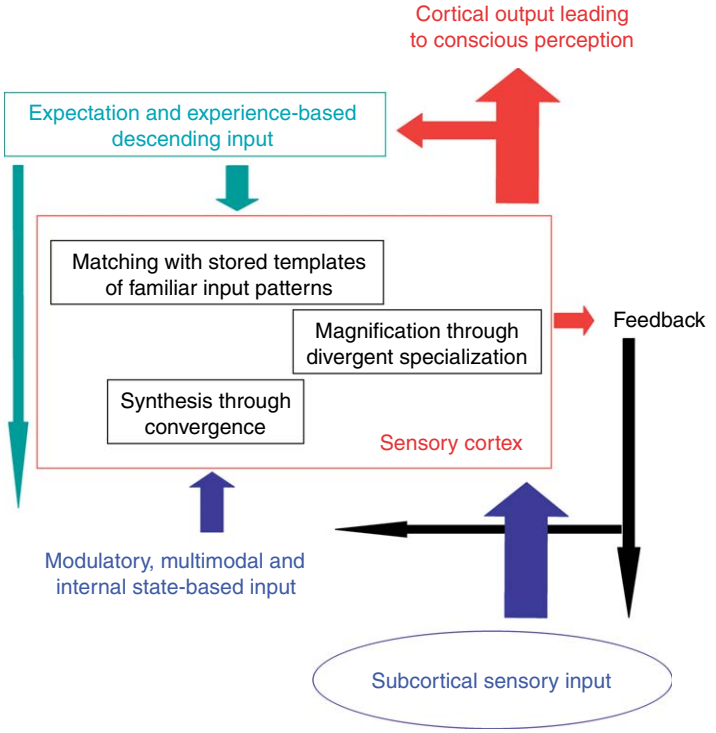

Figure 1 A schematic representation of some of the basic functions ascribed to primary and earlier higher-order sensory cortices. In thalamocortical sensory systems, sensory cortex plays a central role in constructing sensory images from the feature analyzed input it receives, which are ultimately important for conscious perception. Sensory cortex also plays an important role in feedback processes, underlying attention and expectation-induced changes in sensory processing.

percepts, and comparison of afferent activity patterns with stored templates to promote recognition. Furthermore, sensory cortices often embellish this emerging representation with information from other sensory modalities, memory, and emotional and internal state. The second function of sensory cortices is to use the information obtained through these convergent processes to provide feedback to peripheral stages in order to selectively modify gain or acuity, just as sensory cortex itself is under the influence of higher-order cortices. Finally, sensory cortical efferents provide downstream structures with highly processed representations of sensory stimuli and their associated external and internal context to drive behavioral and cognitive outcomes. In effect, sensory cortex can be the first stage of conscious perception.

In performing these functions, sensory cortices utilize at least three basic tools. The first tool is convergence. Stimulus features extracted by peripheral circuits begin to be merged through anatomical convergence in the sensory cortex. Hierarchical processing in the visual system is a classic example, wherein spots of light extracted by center-surround receptive fields in the retina and visual thalamus are merged through anatomical convergence into bars and contrast edges driving visual cortex neurons. Convergence can occur both within a sensory modality, such as the hierarchical visual processing just mentioned, and on a wider scale including disparate regions of sensory cortex as well as potentially including multimodal interactions.

The second tool used by sensory cortices, and directly related to convergence, is synaptic plasticity. Experience-dependent synaptic plasticity is critical for both developmental emergence of local cortical circuits and fine-tuning of those circuits throughout life. This plasticity can allow increased processing power to be devoted to familiar or learned important stimuli by adjusting receptive fields and cortical maps. It can also help to associate stimuli and stimulus features which frequently co-occur to form templates or internal representations of perceptual objects. An advantage of object representation is an increased ability to recognize familiar objects despite degraded inputs or background interference. Finally, synaptic plasticity can allow on-line adjustment of stimulus processing through experience-dependent short-term modulation of synaptic strength.

A third sensory cortical tool is magnification. In nearly all thalamocortical sensory systems, pathways display anatomical organizations laid out as functional sensory maps. Retinotopic, tonotopic, and somatotopic maps are all examples of sensory maps which are expressed within the corresponding sensory cortex. Within each of these cortical maps, cortical space is not divided evenly across sensory space, but rather there are regions of disproportionate investment in specific areas of sensory space. The fovea, which covers a physically very small region of the retina, commands a relatively huge physical proportion of the visual cortex. Similarly, the small range of auditory frequencies corresponding to biologically important sounds (e.g., human voice in humans, echolocating sounds in bats) dominate cortical space within audition. Furthermore, the somatosensory cortex devotes a large region to inputs from the fingers, which account for a relatively small proportion of the human body surface. Thus, cortical processing power, as indexed by cortical volume, is differentially devoted to some regions of sensory world over others, in effect magnifying those stimuli which fall on those receptors. Beyond this magnification in cortical maps, additional cortical space can also be specialized for important stimuli, outside the primary sensory pathway. For example, the fusiform face region in the primate visual system is largely devoted to processing biologically important face stimuli. Similar specializations are seen in other systems, for example the Doppler-shift compensation area in bat echolocating auditory cortex which allows calculation of relative speed of approach toward prey targets.

As we review the structure and physiology of olfactory cortex, the functions and tools used by other sensory systems will be used as guideposts to determine how different (or similar) olfaction is to the other senses. In the following section, we will review the anatomical organization of olfactory cortex, local circuit connectivity, and afferent and efferent connections. We will then review current synaptic and sensory physiological data, followed by an abstraction of general principles of olfactory cortical function.

4.38.2 Cortical Neurocircuitry

The olfactory cortex consists of a collection of laminar structures arranged along the ventrolateral surface of the mammalian brain which receive direct input from olfactory bulb mitral and/or tufted cells (see Figure 2). These target structures include the anterior olfactory cortex, piriform cortex, olfactory

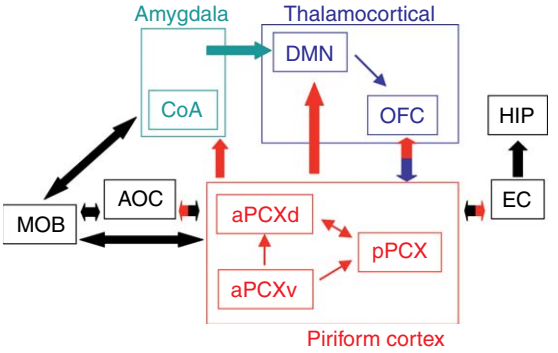

Figure 2 A schematic representation of the major olfactory cortical areas and their interrelationships. Additional details can be found in Cleland T. A. and Linster C. (2003) and Neville K. R. and Haberly L. (2004). This review focuses on the piriform and orbitofrontal cortices. Almost nothing is known regarding the sensory physiology of the anterior olfactory cortex (AOC). MOB, main olfactory bulb; AOC, anterior olfactory cortex; aPXDd, dorsal anterior piriform cortex; aPCXv, ventral anterior piriform cortex; pPCX, posterior piriform cortex; CoA, cortical nucleus of the amygdala; DMN, dorsomedial nucleus of the thalamus; OFC, orbitofrontal cortex; EC, entorhinal cortex; HIP, hippocampus.

tubercle, and the cortical nucleus of the amygdala (Haberly, L. B., 2001). Each of these structures is trilaminar paleocortex, with olfactory bulb afferent input terminating in superficial layer I, a pyramidal cell dense layer II, and a layer III composed of association fiber axons, deep pyramidal cell somata, and interneurons. The olfactory cortex does not express a columnar organization, but rather receives afferent input as a wave of activity spreading caudally through its arrayed dendritic trees. Each of the olfactory cortical structures is interconnected and also project back to the olfactory bulb.

In addition to the paleocortical areas, the olfactory system also includes a thalamocortical pathway, with a projection from the piriform cortex to the dorsomedial nucleus of the thalamus, which in turn projects to the orbitofrontal cortex. The dorsomedial nucleus of the thalamus also receives input from the amygdala and other limbic areas. There are also direct, reciprocal connections between the orbitofrontal cortex and the piriform cortex (Neville, K. R. and Haberly, L., 2004). Orbitofrontal cortex is located anterior in the mammalian brain and juxtaposes piriform cortex along the rhinal fissure in rodents. The orbitofrontal cortex is neocortical in structure and thus displays a six-layer, presumably columnar organization.

While the anatomy of all of these cortical areas dealing with olfaction has been described to some extent in the literature, the piriform cortex has received the most attention. Thus, this review will emphasize piriform cortical structure and function. This emphasis is not meant to imply dominance of the piriform cortex in olfactory processing and perception, but rather, unfortunately, reflects a search where the light is currently brightest. That is, while the piriform cortex, and increasingly orbitofrontal cortex, appear to perform computations of critical importance for the rich experience that is olfactory perception, we simply do not have sufficient data at present to state definitively how areas such as the anterior olfactory cortex and olfactory tubercle contribute.

4.38.2.1 Cortical–Cortical Connectivity

The piriform cortex can be cytoarchitecturally divided into at least four major subregions. In rodents, the anterior piriform cortex is defined as extending caudally from the anterior olfactory cortex to the caudal end of the lateral olfactory tract. Immediately caudal to the anterior piriform cortex lies the posterior piriform cortex. Mitral cell axons no longer lie in a dense tract, but instead diffusely spread in a thin layer across the posterior piriform cortical surface. In addition to this anterior–posterior division, the anterior piriform can be further subdivided into a dorsal and ventral component. Each of these four subdivisions expresses differences in cortical–cortical connectivity and, as more research is performed, increasingly demonstrates differences in sensory physiology (see Section 4.38.3).

The piriform cortex receives direct input from the olfactory bulb, as do all other olfactory cortical structures (see Figure 3). Single mitral/tufted cell axons terminate in small patches in piriform cortex. Mitral cells conveying input from specific olfactory receptor types terminate in overlapping patches in anterior piriform cortex, and even more broadly in posterior piriform (Zou, Z. *et al.*, 2001). The primary target of olfactory bulb input to cortical areas is pyramidal cell apical dendrites.

Pyramidal cells within the piriform cortex can be divided into at least three subgroups, deep pyramidal cells with somata in layer III, pyramidal cells with somata in layer II, and semilunar pyramidal cells with somata in superficial layer II (layer IIa). Each of these neuron classes has spiny apical dendrites extending into superficial layer I. Mitral/tufted cell afferent

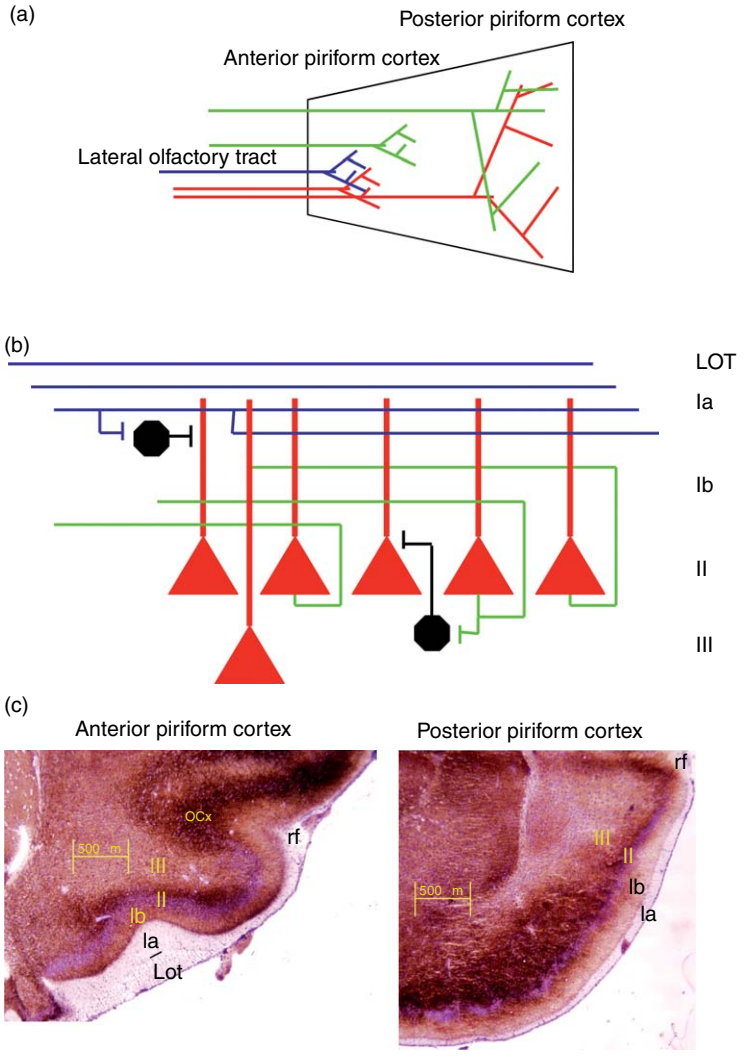

Figure 3 Piriform cortical circuitry. (a) Mitral cells conveying input from olfactory receptor neuron expressing specific olfactory receptor genes terminate in patches in the anterior piriform cortex that overlap with termination zones of mitral cells conveying information from other receptors. Mitral cell termination in the posterior piriform is much more diffuse with information from different receptors broadly overlapping. (b) A schematic representation of piriform circuitry emphasizing lamination of afferent (blue) and association (green) fiber input into trilaminar cortical sheet. Black cells represent local feedforward and feedback inhibitory interneurons. (c) Coronal sections through the anterior and posterior piriform cortex stained with Timm stain for heavy metals which selectively stain intracortical association fiber axons brown and counterstained with cresyl violet. Notice the proportional differences in association fiber input to neurons in dorsal anterior piriform and posterior piriform cortex relative to ventral anterior piriform cortex. rf, rhinal fissure; Ocx, orbital cortex; LOT, lateral olfactory tract.

input to the piriform terminates on the distal most regions of the apical dendrites in cortical layer Ia. Semilunar pyramidal cells may receive largely exclusive excitatory input from mitral/tufted cells, as semilunar cells possess large dendritic spines within layer Ia, but not within layer Ib. Axons of pyramidal cells form the intracortical association fiber system, generally synapsing on spines of both the apical and basal dendrites of other piriform cortical neurons. Individual pyramidal cells have diffuse projections throughout the ipsilateral piriform cortex, and extending into the orbitofrontal cortex and other olfactory cortical areas, the cortical nucleus of the amygdala, as well as the ipsilateral olfactory bulb. Other ipsilateral projects include the dorsomedial nucleus of the thalamus, the hypothalamus, and

entorhinal cortex. These neurons also send axons to the contralateral piriform via the anterior commissure. Semilunar cells also project widely throughout the piriform cortex but do not send feedback to the olfactory bulb. The piriform cortex receives input from a number of areas other than the olfactory bulb, including the entorhinal cortex, orbitofrontal cortex, and amygdala. More complete recent descriptions of local and extrinsic circuitry can be found in Cleland T. A. and Linster C. (2003) and Neville K. R. and Haberly L. (2004).

Olfactory areas also receive input from a variety of modulatory systems, including the noradrenergic nucleus locus coeruleus, the cholinergic horizontal limb of the diagonal band, and serotonergic raphe nucleus. These systems have been shown to play important roles in olfactory cortical function and plasticity (see Section 4.38.3).

In addition to pyramidal cells, there are a variety of classes of inhibitory interneurons. Interneurons in layer I appear to receive input from the lateral olfactory tract and in turn synapse onto apical dendritic shafts of piriform cortical pyramidal cells in a feedforward inhibitory circuit. Interneurons with somata in layer III receive input from pyramidal cell axon collaterals and feedback onto neighboring pyramidal cell somata and basal dendritic shafts. However, extensive variations from these canonical patterns exist (Neville, K. R. and Haberly, L., 2004).

4.38.2.2 Piriform Cortex Synaptic Physiology

Mitral/tufted cell axons terminating on distal apical dendrites of piriform cortical pyramidal neurons release glutamate as a neurotransmitter (Jung, M. W. *et al*., 1990). Both AMPA and NMDA receptors are located postsynaptically on pyramidal cell apical dendrites. Mitral/tufted cell presynaptic terminals express metabotropic glutamate receptors, as well as receptors for modulatory inputs such as norepinephrine. Activation of NMDA receptors appears to be regulated in part by apical dendritic inhibition mediated by layer I gamma-aminobutyric acid (GABA)ergic interneurons. Layer III GABAergic interneurons synapse heavily on pyramidal cell somata and induce current shunting inhibition. Thus, these two forms of inhibition can be both anatomically and functionally distinct.

Activation of the lateral olfactory tract evokes an excitatory postsynaptic potential (EPSP) in the distal half of the pyramidal cell which, due to the electrotonic distance, can be reduced by 75% at the cell body (Ketchum, K. L. and Haberly, L. B., 1993). Depolarization of pyramidal cells to spike threshold activates the glutamatergic association fiber system, and thus within approximately 5 m, the afferent-evoked EPSP is followed by an association fiber-evoked EPSP. These EPSPs are due to activation of synapses in the proximal half of the apical dendrite; thus, they decay much less than lateral olfactory tract-evoked EPSPs. The association synapse-mediated EPSPs, however, coincide with feedback inhibitory portrynaptic potentials (IPSPs). Following this initial rapid sequence of synaptic events, a later, prolonged K^+-mediated IPSP is apparent. This sequence of events can initiate oscillatory (gamma frequency) activity within the piriform following a single afferent volley as association fiber activity circulates throughout the piriform. Single-unit activity in the piriform has been shown to occur in phase with the gamma frequency oscillation, as would be expected given its generation mechanism (Eeckman, F. H. and Freeman, W. J., 1990).

Modulatory inputs to the piriform cortex appear to have differential effects on the afferent and intrinsic fiber pathways. Both acetylcholine and norepinephrine have direct effects on piriform cortical neurons, but interestingly they also have presynaptic effects on synaptic transmission. Both acetylcholine and norepinephrine preferentially depress association fiber excitatory synapses, while having minimal impact on lateral olfactory tract afferent input (Hasselmo, M. E. *et al*., 1990; Hasselmo, M. E. and Bower, J. M., 1992).

Both lateral olfactory tract and association fiber synapses express use-dependent plasticity that may be involved in piriform cortical odor information processing. As described below, lateral olfactory tract synapses express a short-term depression following intense electrical or odor-evoked activation that recovers within 2 min (Best, A. R. and Wilson, D. A., 2004). This depression is composed of two phases, a short (<15 s) phase that is consistent with neurotransmitter depletion and a longer phase (<2 min) that can be blocked by antagonists of presynaptic group III metabotropic glutamate receptors (Best, A. R. and Wilson, D. A., 2004).

Lateral olfactory tract and the association fiber synapses also express long-term potentiation, though potentiation of the lateral olfactory tract synapses appear minimal at best (Neville, K. R. and Haberly, L., 2004). The association fiber synapses display

robust (20–30%), NMDA receptor-dependent, long-term potentiation. Theta burst stimulation paradigms, which involve short gamma (40–100 Hz) frequency bursts of pulses with the burst delivered at theta (5–10 Hz) frequency appear most effective at inducing long-term potentiation in association fiber synapses. These stimulation parameters roughly match what would occur during active sniffing at theta frequency.

This physiology and pharmacology suggests a particularly important role for association fibers in piriform cortical function and plasticity. Association fibers are electrotonically closer to the somata, are more plastic, and more strongly influenced by modulatory inputs than is the primary cortical afferent. The differential roles of these two excitatory cortical pathways in information processing by olfactory cortex are discussed below.

4.38.2.3 Olfactory Thalamocortical Pathway Functional Anatomy

In addition to the direct olfactory bulb input to the primary olfactory cortical areas, the olfactory pathway also includes a thalamic representation and a thalamocortical projection. The piriform cortex projects to the mediodorsal thalamic nucleus which in turn projects to the orbitofrontal cortex (and other prefrontal regions). The mediodorsal thalamus also receives input from the cortical and basal nuclei of the amygdala, potentially enriching the olfactory input to orbitofrontal cortex with emotional context (Schoenbaum, G. *et al*., 2003a). The orbitofrontal cortex also receives direct input from piriform cortex, in addition to its thalamic input, leading to a convergent triangulation between piriform, mediodorsal thalamus, and orbitofrontal cortex. As in the piriform cortex, orbitofrontal neurons respond not only to specific odors, but also to odor-contextual cues (Schoenbaum, G. and Eichenbaum, H., 1995; Rolls, E. T., 2004). Orbitofrontal cortex neurons also respond to specific odor-taste compounds, potentially contributing to taste and odor hedonics.

The specific functions of thalamocortical olfactory pathways in odor perception are not known. Lesions of the dorsomedial thalamus in rats impair learning and memory of discriminative odor cues, although this impairment appears to not be related to odor discrimination per se, but rather may represent a memory disruption (Zhang, Y. *et al*., 1998).

Single neurons in the orbitofrontal cortex of both rodents and primates encode both odor quality and odor associations. In primates, both the identity of an odor being inhaled and its reinforcement value and taste associations can be extracted from orbitofrontal cortex neuron spike trains (Rolls, E. T., 2004). Odor quality is encoded very sparsely in orbitofrontal cortex, and there is diversity in responses with, for example, some neurons encoding odor quality independently of reinforcement associations and some encoding the reinforcement associations. Similar results have been seen in rat orbitofrontal cortex and have led to the suggestion that the orbitofrontal cortex integrates sensory representations with associated reward value to help guide motivated behavior – a conclusion supported by lesion studies (Schoenbaum, G. *et al*., 2003b). Given the interconnectivity between the orbitofrontal and piriform cortices, however, the specific role of thalamocortical inputs versus cortical–cortical inputs to orbitofrontal cortex in this higher-order sensory representation is unknown. It is interesting to speculate that the orbitofrontal cortex may serve in part in a magnification role as discussed above, providing dedicated additional processing support for hedonically important odors beyond that performed in the piriform cortex.

4.38.3 Cortical Sensory Physiology

Despite the wealth of information regarding olfactory cortical circuitry and synaptic physiology, our understanding of olfactory cortical sensory physiology lags far behind most other sensory systems. As more knowledge is gained as to the nature of sensory information being fed into the cortex, and as more people turn centrally to understand how the outcome of peripheral coding is acted upon by cortical circuits, this lag should be rapidly reduced. This section will review our current state of understanding regarding cortical coding of odor intensity, quality, familiarity, and context. Sensory physiological and computational work suggests that the piriform cortex is critically involved in synthetic coding of complex odorants and in some cases their nonolfactory contexts, gating olfactory information flow relative to experience and behavioral state, and creating templates of familiar and learned odorants which facilitates recognition and discrimination.

4.38.3.1 Odorant Intensity

Piriform cortical representation of odor intensity has been sorely understudied. Intensity codes in other

systems include a variety of options. Firing rate of individual neurons can be correlated with stimulus intensity. Similarly, the number or type of activated neurons can change with intensity. For example, there may be neurons with differing thresholds that are preferentially activated by high or low intensities. Finally, temporal patterning of individual or ensemble activity may be correlated with stimulus intensity.

Recently, Sugai and colleagues have examined the spatial extent of piriform cortical activation by odors of varying intensity (Sugai, T. *et al.*, 2005). Using a combination of intrinsic signal imaging and single-unit recording in the dorsal anterior piriform cortex, these authors report a rostral to caudal spread of activity as odor concentration increases. Thus, single units in caudal regions of the dorsal anterior piriform cortex had higher-odor thresholds than more rostral cells. Interestingly, these results correspond with findings that superficial tufted cells in the olfactory bulb project more heavily to rostral portions of the piriform cortex and are more responsive to olfactory nerve input compared to internal tufted or mitral cells which have higher thresholds and project more caudally. Thus, the differential sensitivity and projection patterns of cortical afferents could produce a rostral to caudal gradient of odor sensitivity across the piriform cortex.

It should also be noted that that there is a rostral to caudal gradient of cortical feedback to the olfactory bulb, wherein more caudal olfactory cortical neurons terminate on deep granule cells and more rostral cortical neurons terminate on more superficial granule cells. Deep granule cells are believed to synapse preferentially with mitral and internal tufted cells, while superficial granule cells may preferentially synapse with middle or external tufted cells. Thus, the rostral to caudal sensitivity gradient in cortex could be a part of a closed feedback loop to specific populations of olfactory bulb output neurons. Tufted and mitral cells also display differential phase locking to the respiratory cycle, with tufted cells firing earlier in the respiratory cycle than mitral cells, potentially creating rostral–caudal temporal gradients in cortical activity relative to intensity as well.

One important issue that the olfactory cortex must deal with, however, is that the afferent input to the cortex may change with stimulus intensity. Olfactory receptors, olfactory glomerular layer spatial patterns, and mitral/tufted output are all modified by changes in stimulus intensity. Some odorants change in perceptual quality as stimulus intensity increases; however, most odorants are qualitatively stable over many orders of magnitude of concentration (Laing, D. G. *et al.*, 2003). Therefore, cortical circuits described below may be particularly important for maintaining odorant-specific patterns of cortical output across concentration range, thus maintaining perceptual quality despite intensity-induced changes in afferent input.

4.38.3.2 Odorant Quality

Cortical coding of odorant quality ultimately involves two levels of information. At one level, cortical odorant quality encoding may reflect the structural make-up of the inhaled stimulus – essentially a reflection of the sum of the odorant features extracted by more peripheral circuits. However, odor perception must involve coding beyond a simple reflection of convergent input. For example, structurally similar molecules (similar collections of features) can smell quite different, and similar smells may derive from structurally dissimilar molecules. Furthermore, the perceived smell of a banana is relatively stable, regardless of the background odorants inhaled at the same time whose components should mix with those of the banana at the receptor sheet. Finally, the integral hedonic quality of that banana smell perception is dependent on current internal state (e.g., hunger vs. nausea) and expectations. Thus, a full account of cortical odorant quality coding (and ultimately odor perception) must go beyond simple description of responses to isolated monomolecular stimuli and begin to describe such higher-order perceptual quality phenomenon as mixture synthesis, sensory gating, figure-ground separation, and the effects of expectation.

In fact, an examination of odorant receptive fields of piriform cortical neurons (see Figure 4) suggests superficial similarity to those of olfactory bulb mitral/tufted cells. Individual cortical neurons respond to multiple odorants (Wilson, D. A., 1998; 2000; Litaudon, P. *et al.*, 2003) and demonstrate differential responsiveness to odorant features such as carbon chain length (Wilson, D. A. and Stevenson, R. J., 2003). Selectivity for simple odorants is increased in neurons in posterior piriform compared to anterior piriform cortex (Litaudon, P. *et al.*, 2003), and in fact appears to increase as one moves from piriform to orbitofrontal cortex (Tanabe, T. *et al.*, 1975), suggesting a possible refinement of odorant identity coding in a hierarchical manner.

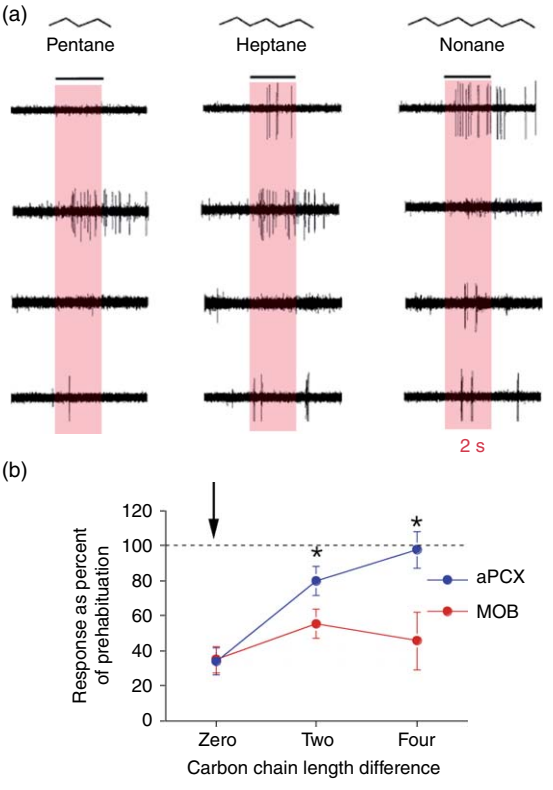

Figure 4 Examples of anterior piriform cortex single-unit responses to odorant stimuli. (a) Responses of four different anterior piriform cortical neurons to second stimuli presented during the red-shaded region. Note that, similar to reports of olfactory receptor neurons and mitral/tufted cells, piriform cortical neurons respond differentially to odorants varying along a specific dimension such as carbon chain length. (b) However, using a cross-adaptation procedure to determine odorant discrimination abilities of these neurons revealed that cortical neurons were significantly better at discriminating between odorants within their receptive fields than mitral/tufted cells of the main olfactory bulb (MOB). aPCX, anterior piriform cortex.

In contrast to a possible intensity-dependent spatial activation of the piriform cortex described above, initial attempts to describe odorant quality-dependent spatial patterns of piriform cortical activation were largely unsuccessful. Studies utilizing 2-deoxyglucose metabolic activity imaging, intrinsic signal imaging, voltage sensitive dye imaging, and immediate early gene immunohistochemistry (Litaudon, P. *et al.*, 1997; Illig, K. R. and Haberly, L. B., 2003; Sugai, T. *et al.*, 2005) have all failed to detect precise monomolecular odorant quality-specific patterns of piriform cortex activation comparable to those seen in the olfactory bulb.

Illig K. R. and Haberly L. B. (2003) reported (see Figure 5) that monomolecular odorant stimulation evoked rostrocaudal bands of c-fos labeling of pyramidal cells in anterior piriform cortex. However, these bands appeared to correspond primarily with the anatomical subdivisions of the anterior piriform more than demonstrate an odorant-specific pattern. Thus for example, most odorants more strongly activated the dorsal anterior piriform and a narrow band of ventrally located cells than the intermediate regions of the anterior piriform cortex. The authors suggested that there may be subtle variations in c-fos labeling that could be odor specific, but that there were no clear odorant-specific patches evident.

Recent work by the Buck laboratory using a more diverse odorant set and more quantitative analyses of odorant-evoked Fos-staining patterns suggests there may in fact be regional specificity in response to odorants within the anterior piriform cortex (Zou, Z. *et al.*, 2005). Structurally similar odorants evoke odorant-specific spatial patterns of neural activation within the anterior piriform cortex. Activated neurons are dispersed within activated regions; thus individual neighboring neurons do not necessarily have similar response properties. Similarly, mapping of single-unit odorant responses and cell locations shows no strong spatial clustering of neurons responsive to molecularly and perceptually dissimilar odorants in anterior piriform cortex (Kadohisa, M. and Wilson, D. A., 2006), though this has not yet been thoroughly investigated.

If the piriform cortex processes odors as synthetic objects built through experience as discussed elsewhere, then perhaps strong spatial clustering or mapping of activity evoked by particular odorants would not be expected. For example, although inferotemporal visual cortical neurons responding to a particular visual object lie within a particular cortical column, neighboring columns may contain neurons responding to completely different visual objects (Tanaka, K., 2000; see Figure 6). As experience throughout life shapes the tuning properties of these cortical neurons, objects become encoded by randomly scattered cortical neurons, with neurons maximal responsive to ball objects, located next to neurons responsive to tree objects and star-shaped objects. Similarly, we predict that the location of piriform cortical neurons responding to odor objects will not conform to a consistent organized map, but rather show discontinuities. This effect may be more pronounced in posterior piriform than in anterior

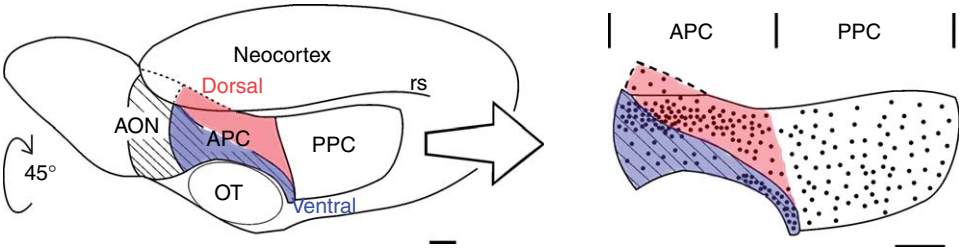

Figure 5 Odorant-evoked neural activity in the piriform cortex as revealed by c-fos immunohistochemistry (Illig, K. R. and Haberly, L. B., 2003). (Left) Image of the rat brain viewed from the side with the subregions of the piriform cortex displayed. (Right) Patterning of activated neurons in response to odorant stimulation. No distinct odorant-specific differences were noticed in activation patterns in piriform, although distinct subregion differences in odorant responsiveness were noted. Recent work by Zou Z. *et al.* (2005), using similar techniques, suggests that odorant-specific patterning may be present in the anterior piriform. Both studies clearly demonstrate that odorant-evoked activity is dispersed, with individual neighboring neurons responsive to different odorants. It must be noted, however, that the techniques used would not reveal neurons with rapidly adapting responses (Wilson, D. A., 1998). APC, anterior piriform cortex; PPC, posterior piriform cortex. Image adapted from original image provided by Kurt Illig.

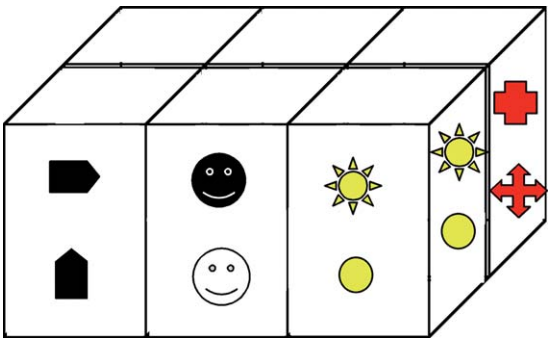

Figure 6 Schematic representation of the spatial organization of visual object encoding in the primate visual inferotemporal cortex. Although primary visual cortex is highly and predictably organized, in inferotemporal cortex where neurons have receptive fields for visual objects, the organization is less predictable. Neurons within a single column may have receptive fields for similar objects, perhaps at different views or angles, but neurons in neighboring columns may have receptive fields for completely different objects. Such a dispersed organization may also be expected to occur in piriform cortex for odor objects. Adapted from Tanaka, K. 2000. Mechanisms of visual object recognition studied in monkeys. Spat. Vis. 13, 147–163.

piriform as association fibers come to dominate excitatory control.

While much of sensory physiology in the olfactory system has focused on monomolecular odorants, most odorants experienced in nature are complex mixtures. However, as noted above, while composed of often hundreds of different components, these natural mixtures are perceived as individual, indivisible odor objects. For at least 20 years, the piriform cortex has been seen as a possible site of synthetic odor quality processing in olfaction. Mitral/tufted cells, conveying information about specific odorant features (Fletcher, M. L. and Wilson, D. A., 2003; Lin da, Y. *et al.*, 2005), converge onto individual piriform cortical pyramidal cells through overlapping, patchy axonal termination zones (Zou, Z. *et al.*, 2001). Thus, through simple coincidence detection, single cortical neurons could transmit information concerning the occurrence of specific combinations of odorant features. However, simple coincidence detection is insufficient to account for complex odor processing such as occurs in odorant figure-ground separation (Kadohisa, M. and Wilson, D. A., 2006) (see Section 4.38.4.3). In the situation where odorants are experienced against a background (nearly all situations), those odorants would be merged with the background based on their coincident inhalation resulting in context-variant odor perception of stable objects. This does not generally occur, and thus a separate mechanism, beyond simple afferent coincidence detection, must be invoked.

Intracortical association fibers and synaptic plasticity may solve the problem of stable odor representations regardless of background, and often regardless of variations in stimulus make-up or intensity. As noted above, single piriform cortical neurons have axon collaterals broadly dispersed throughout the piriform cortex (Johnson, D. M. *et al.*, 2000). Unique combinations of mitral cell-mediated odorant feature input should activate a unique ensemble of piriform cortical pyramidal neurons, based on termination patterns of those mitral cell axons. In some cases, individual cortical neurons will receive convergent input from mitral cells

conveying information regarding two or more odorant features, and in other cases a cortical neuron may receive input regarding a single odorant feature, depending on the pattern of mitral cell–cortical connectivity. Cortical pyramidal cells sufficiently activated by this input in turn activate additional cortical neurons via the intracortical association fibers, thus greatly expanding the combinatorial activation of single cortical neurons.

Specifically, imagine an odorant composed of features A, B, and C. Each of these features is recognized by individual mitral cells which convey processed feature information to the cortex. Through simple anatomical convergence and coincidence detection, individual cortical neurons receive partial combinatorial information (AB, AC, and BC), depending on the initial state of afferent connectivity for each cortical neuron (it should be noted that odor experience early in development can modify overall mitral cell termination patterns in piriform cortex) (Wilson, D. A. *et al*., 2000).

Pyramidal neurons activated by these partial combinations can then, via intracortical association fibers, create more complete combinations on other cortical neurons, resulting in an ensemble of neurons driven by the complete ABC mixture. This process can occur passively on each new presentation of ABC through coincidence detection. However, given the subtle variations inherent in naturally occurring complex mixtures (with exceptions for tightly controlled pheromonal mixtures), including variation in mixture component ratios, variation in overall intensity, occasional missing or extra components, each new presentation of that mixture may evoke a different ensemble of cortical neuron activation, and in turn a different percept. Plasticity of intracortical association fiber synapses, and creation of stored templates of previously experienced patterns of input, could allow perceptual stability of complex mixtures over time.

In effect, the piriform cortex has been hypothesized to function as a form of auto-associative, content-addressable memory. Circuits using content-addressable memory allow an input pattern to be entered, and then the entire memory array circuit is searched to determine whether that pattern exists in the stored memory, and in some cases identifies other items associated with that pattern. This process is distinct from common computer random access memory wherein the input is an address or storage site and the output is the contents of that site. Thus, content-addressable memory allows familiar input patterns to be recognized, completed and elaborated upon, even in the face of degraded input. As input patterns become more divergent, they activate different memory templates, and thus different odorant representations. In contrast, two well-learned representations can involve very similar inputs and yet evoke distinctly separate stored representation.

Cortical content-addressable memory can rely on associative synaptic plasticity such as long-term potentiation described above. As combinations of odorant features co-occur, association fibers conveying information about these features and their combinations are strengthened through associative plasticity (Haberly, L. B., 2001). On subsequent presentation of the experienced, familiar pattern, circuits containing these now strengthened synapses are more easily activated – signaling a matched template. If the input pattern is degraded or slightly modified, the template pattern can be completed because of the enhanced synaptic strength (Hasselmo, M. E. and Barkai, E., 1995). In fact, with experience, anterior piriform cortical neurons learn to distinguish binary mixtures from their components (Wilson, D. A., 2003). Through this process, odor experience and familiarization come to have strong effects on odor discrimination and perceptual stability (Wilson, D. A. and Stevenson, R. J., 2003). In fact, pharmacological disruption of normal synaptic plasticity within the piriform cortex can disrupt experience-induced enhancement in cortical odorant discrimination. Furthermore, when content-addressable memory is combined with selective cortical afferent adaptation, the piriform can begin to perform more complex functions such as figure-ground separation (see below).

There is a distinct difference in the relative contribution of the afferent lateral olfactory tract and the intrinsic association fiber system to the anterior and posterior regions of the piriform cortex. The anterior piriform cortex is dominated by excitatory input from the lateral olfactory tract, as evidenced both anatomically (see Figure 3) and physiologically. In contrast, the posterior piriform cortex is dominated by association fiber excitatory activity from both within the piriform cortex and from other cortical areas. For example, local field potential oscillations recorded in the anterior piriform cortex are similar in frequency characteristics and strongly coherent with the olfactory bulb, while the oscillations in the posterior piriform are more similar to, and strongly coherent with, the entorhinal cortex. In light of the association fiber plasticity described above, this

difference suggests that odor quality representations by ensembles of neurons within these two areas may also differ substantially.

In the only comparison of anterior and posterior piriform single-unit activity, Litaudon and colleagues reported that cells in posterior piriform showed less spontaneous activity and responded to fewer odors than cells in the anterior piriform cortex (Litaudon, P. *et al.*, 2003). Posterior cortical cells were more diverse in their activity phase relationship to the respiratory cycle than were anterior cells, again suggesting a reduced reliance on lateral olfactory tract-driven activity and more on association fiber activity. Precise comparisons of odorant receptive fields or responses to complex odor mixtures and learned odor objects were not made, although the reduced odor responsiveness in the posterior hints at a more narrow tuning.

We are currently examining the effects of familiarity with odorant mixtures on responses to mixtures and their components in the anterior and posterior piriform cortex, with the hypothesis that posterior neurons may become highly selective for familiar mixtures. In fact, in several studies of piriform cortical responses to novel binary mixtures, cells responding selectively to the mixture, without also responding to one or both of the components, are extremely rare (Kadohisa, M. and Wilson, D. A., 2006). It is hypothesized that as odor mixtures become more familiar, piriform cortical neurons, perhaps especially posterior cortical neurons, will enhance their responsiveness to the familiar mixtures independent of their existing responsiveness to the components alone. This could result in stimulus response patterns similar to that observed in visual inferotemporal cortex, wherein single units may respond vigorously to a visual object (e.g., a face) yet not to components of the object if presented in isolation (Figure 7).

The preceding discussion of odorant quality coding has focused on the structural aspects of odorant molecules as the discriminant variable. Ultimately, of course, odor quality encoding moves away from molecular structure toward perceptual objects, where similar molecular structures may have distinctly different odor qualities, and different molecular structures can evoke similar odor qualities. Recent human cortical fMRI imaging works confirms that perceptual odor quality is a cortical phenomenon. Using a creative cross-habituation paradigm, Gottfried and colleagues suggest that the human anterior piriform cortex encodes information about the structural conformation of odorants (e.g., aldehydes cross-adapt with aldehydes regardless of their perceptual quality), while the posterior piriform cortex encodes the perceptual conformation of odors (e.g., fruity odors cross-adapt with fruity odors

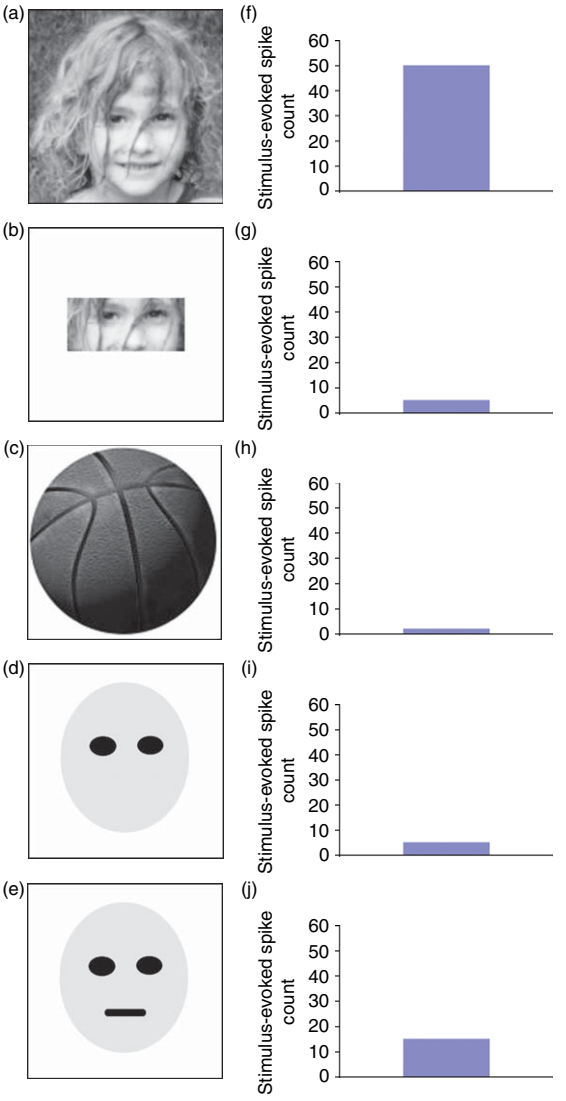

Figure 7 Representation of single-unit response properties in primate visual inferotemporal cortex. Individual inferotemporal neurons have receptive fields for visual objects and are often much less responsive or nonresponsive to individual features of those objects. These receptive fields emerge with experience and are believed to be dependent on plasticity of intracortical association fiber synapses. Similar response properties are predicted for familiar complex odor objects and their components in piriform cortex. Adapted from Tanaka, K. 2000. Mechanisms of visual object recognition studied in monkeys. Spat. Vis. 13, 147–163.

regardless of their structural make-up). These data, if confirmed, are an excellent example of the emergence of odor quality through synthesis within the piriform cortex. Similarly, presentation of the odorant isovaleric acid can produce the perception either of cheese or of an unpleasant percept of vomit or body odor. When subjects were informed they were smelling cheese, the orbitofrontal cortex was activated. However, when the same molecular stimulus was labeled as body odor, the orbitofrontal cortex was not activated (DeAraujo, I. E. *et al.*, 2005). This strongly suggests that perceptual odor quality is an emergent property of the cortical synthesis of odorant input with multimodal, internal state, and expectation information to create a unique perceptual object.

A final point regarding encoding of odor quality in the piriform cortex involves multimodal, hedonic, and context-dependent components of the representation. As discussed in more detail below, cortical odor representations – similar to their perceptual outcome – can be multifaceted. The smell of an orange can include taste components (e.g., sweet), hedonic components (which may vary depending on recent experience, e.g., sensory specific satiety), and even visual imagery components (e.g., visual imagery of the color or of the fruit). Olfactory cortical areas, including both the piriform cortex and the orbitofrontal cortex, can serve as sites of multimodal and hedonic convergence (Schoenbaum, G. and Eichenbaum, H., 1995; Rolls, E. T., 2004), which may allow for the richness of odor quality perception.

In summary, cortical coding of odor quality appears to go far beyond a simple read-out of peripheral odorant feature extraction, allowing for a synthetic process wherein cortical odor coding and odor perception are shaped by past experience. Experience-dependent cortical synthetic processing enhances discriminability and perceptual constancy of familiar odors and adds multimodal complexity to odor quality representations. The cortical circuitry underlying these phenomena is characteristic of an auto-associative, content-addressable memory system, relying on synaptic plasticity of the intrinsic association fiber system to store templates of familiar patterns of afferent input. In accord with this view, disruption of cortical synaptic plasticity disrupts experience-dependent cortical odorant quality discrimination. Given this view of cortical odor representation, it is hypothesized, and generally supported by the data, that odor quality will be encoded by dispersed ensembles of cortical neurons, with minimal clustering of cells sharing similar tuning characteristics. It must also be emphasized that quality discrimination of familiar odorants occurs very rapidly in both freely breathing animals and humans, general within a single sniff. The memory-based process described here could facilitate this rapid processing.

4.38.3.3 Sensory Gating

In addition to serving as the primary site of synthesis and recognition of perceptual objects, sensory cortex is also a critical component of the circuitry underlying attention and sensory gating. Cortical processing resources can be differentially allocated over perceptual space and time depending on internal state and arousal, recent stimulation history, and cognitively directed attention. In olfaction, evidence has been obtained for a direct role of the anterior piriform cortex in sensory gating related to both internal state and recent stimulation history.

In thalamocortical sensory systems, the sensory-evoked activity of thalamic neurons is modulated by arousal and the sleep–wake cycle. For example, in the auditory system of restrained, unanesthetized guinea pigs, tone-evoked responses of auditory thalamic neurons decrease in magnitude and become more selective during slow-wave sleep compared to waking (Edeline, J. M. *et al.*, 2000). These changes appear to occur within the thalamus, as subthalamic activity is either not modulated or variably modulated by sleep–wake cycles. The decrease in thalamic excitability appears to be mediated by a membrane hyperpolarization during slow-wave sleep, presumably driven by changes in modulatory input. The decreased thalamic response during slow-wave sleep still allows accurate throughput of frequency-specific information to the cortex, however at a much reduced level (Edeline, J. M. *et al.*, 2000).

In the olfactory system, a similar state-dependent modulation of information transfer occurs, though it appears in the anterior piriform cortex. In urethane anesthetized rats, which display electrographic evidence of spontaneous slow-wave and fast-wave neocortical EEG transitions, anterior piriform cortical neurons decrease their responsiveness to odor input during the slow-wave state (comparable to slow-wave sleep) relative to responsiveness during the fast-wave state (perhaps comparable to awake or fast-wave sleep states) (Murakami, M. *et al.*, 2005). Electrical stimulation of the brainstem which shifts activity between these two states similarly modifies

cortical odorant responsiveness. Olfactory bulb evoked activity is not reliably modified in a state-dependent manner, suggesting a piriform cortical origin for these changes. In fact, similar to the mechanism of thalamic modulation, anterior piriform cortical neurons show a hyperpolarization during the slow-wave state that can account for the reduced sensory responsiveness (Murakami, M. *et al.*, 2005). Whether similar changes occur in olfactory thalamus is not known.

A second form of sensory gating is based on recent stimulation history and is commonly associated with adaptation or habituation to background or currently nonsignificant stimuli. In thalamocortical systems, precise mechanisms of sensory habituation have not been determined. In general, however, adaptation to prolonged or repeated stimuli tends to be most pronounced in the sensory cortex compared to subcortical areas. Two specific mechanisms for cortical adaptation have been suggested. First, similar to the state-dependent gating mechanism described above, in the visual system, there is evidence for a sensory-dependent hyperpolarization in visual cortical neurons following prolonged stimulation (Carandini, M. and Ferster, D., 1997). As with state-dependent gating, this hyperpolarization could reduce excitability and sensory-evoked responses in cortical neurons. A second proposed mechanism in thalamocortical systems is a stimulation-dependent synaptic depression of thalamic inputs to visual sensory cortex (Chung, S. *et al.*, 2002). Synaptic depression has also been proposed as a mechanism of adaptation of brainstem-mediated acoustic startle reflexes.

In the olfactory system, neurons in the anterior piriform cortex express significantly more rapid and complete adaptation to prolonged or repeated odor stimulation than their subcortical afferents, mitral/tufted cells in the olfactory bulb (Wilson, D. A., 1998). In awake animals performing a simple odor task, piriform neurons rapidly reduce their odor responses to a short burst of a few spikes (McCollum, J. *et al.*, 1991). In anesthetized animals, the adaptation is odorant specific, expressed in both evoked firing and subthreshold postsynaptic potentials, and recovers within 2 min following a 50 s odorant exposure. There is no corresponding hyperpolarization to account for the decreased odor responsiveness (Wilson, D. A., 1998). However, intracellularly recorded postsynaptic potentials in response to both odorant stimulation and electrical stimulation of the lateral olfactory tract are transiently depressed during and after prolonged odorant exposure (Wilson, D. A., 1998). These results suggest that synaptic depression of cortical afferents may underlie short-term cortical odorant adaptation.

To test this hypothesis, the synaptic depression evoked by odorant exposure was modeled in vitro using patterned electrical stimulation of the lateral olfactory tract in slices of anterior piriform cortex. Electrical stimulation of the lateral olfactory tract in vitro, in a manner meant to mimic odorant-evoked mitral cell activity, induced a short-term synaptic depression, with a magnitude and duration similar to that of odorant exposure-induced cortical odor adaptation (Best, A. R. and Wilson, D. A., 2004). This synaptic depression could be blocked by the metabotropic glutamate receptor group II/III (mGluRIII) antagonist CPPG. mGluRIII receptors are expressed on the presynaptic terminals of mitral cell axons, and when activated, reduce neurotransmitter release. *In vivo*, bilateral infusion of CPPG into the anterior piriform cortex prevents adaptation of both cortical and simple behavioral responses to odorants (Best, A. R. and Wilson, D. A., 2004; Best, A. R. *et al.*, 2005). These studies are the most complete mechanistic description of sensory adaptation in any mammalian sensory system and demonstrate the power of taking advantage of the relatively simple structure of the olfactory system to address questions of this nature.

Rapid cortical adaptation in the olfactory system may not only be important for reducing responses to persistent stimuli, but also may play an important role in olfactory figure-ground separation. The piriform cortex can function as a high-pass filter, responding most strongly to new stimuli and much less so to stable stimuli. As odorants are encountered against a background, the piriform cortex can respond as if these new odorants were in isolation. In contrast, under similar conditions, mitral/tufted cells respond to the actual inhaled stimulus – a mixture of background and new additive. Rapid cortical adaptation thus can allow the piriform cortex to selective read olfactory bulb output, ignoring temporally stable components (background) while remaining responsive to novel stimuli occurring against this background (Kadohisa, M. and Wilson, D. A., 2006).

Cortical adaptation may also play a role in modulation of cortical responsiveness to food stimuli based on recent feeding patterns. Sensory-specific satiety is a decrease in behavioral responsiveness to a particular food stimulus (e.g., banana's) following

prolonged feeding with that stimulus. The behavioral satiety can be highly stimulus specific (Rolls, E. T., 2004). In primates, behavioral sensory-specific satiety is associated with a corresponding decrease in responsiveness of orbitofrontal cortex neurons to that stimulus.

Together, these descriptions of state-dependent and experience-dependent sensory gating suggest a role for anterior piriform cortex that combines both thalamic and cortical components of sensory gating in thalamocortical systems. The state-dependent process and mechanism mediated by thalamic neurons in other sensory systems is expressed in anterior piriform cortical neurons in olfaction. Similarly, the experience-dependent adaptation mediated by cortical neurons in other sensory systems is expressed in anterior piriform cortical neurons in olfaction. The separation of these two function in thalamocortical systems may be in response to differences in the nature of the stimulus representation or other information processing demands in these nonolfactory sensory systems.

A third form of sensory gating – cognitively directed attention – has not been explored to any major extent in olfaction. Attention has been likened to a searchlight, wherein differential processing power can be devoted to some portions of a sensory scene compared to other portions of the same scene (Crick, F., 1984). This may be most easily imagined as occurring in the visual or auditory systems. An example might include switching auditory attention between different, simultaneously occurring conversations. It is not clear whether a similar phenomenon exists in olfaction, although it is anecdotally possible to adapt to a background odor and then redirect attention toward that odor and begin to perceive it again.

In thalamocortical sensory systems, the thalamic reticular nucleus may play an important role in the attentional search light. The thalamic reticular nucleus is a thin lamina of neurons along the superficial edge of the thalamus and is organized both topographically and according to modality. For example, a subset of reticular thalamic neurons receive input from visual cortex and project to visual lateral geniculate nucleus neurons in a retinotopic manner. The reticular thalamus receives excitatory input from both sensory thalamus and sensory cortex, and projects back to sensory thalamus. Importantly, this feedback to sensory thalamus is inhibitory. Thus, the reticular thalamus is a group of inhibitory neurons, receiving cortical feedback (as well as state-dependent modulatory inputs) and capable of gating the flow of thalamic information to the sensory cortex. The reticular thalamus thus could play a role in attentional changes in sensory coding, through enhancing processing of important information while suppressing processing of unimportant or unexpected information.

Although data on olfactory-directed attention and scene analysis are limited at best, it is interesting to note a potential olfactory circuit analogy to the reticular thalamic circuit described above. Olfactory bulb granule cells monitor mitral cell output via dendrodendritic synapses and receive axosomatic and axodendritic synapses from cortical feedback fibers. While several hypotheses exist regarding the role of mitral–granule cell reciprocal connections in lateral and feedback inhibition, these hypotheses largely overlook the impact of huge excitatory input to granule cells from olfactory cortical areas. Olfactory cortical feedback to the bulb could provide a higher-order modulation of granule cell excitability, resulting in top-down control of olfactory processing of sensory afferent activity. This cortical modulation of granule cell excitability could be evidenced by changes in gamma frequency local field potential oscillations during periods of strong descending input to the bulb, just as has been found in freely behaving animals performing well-learned olfactory behaviors, as described above. Thus, the olfactory cortex, through descending control based on attention and expectancy, could modulate how the olfactory bulb processes odors (Kay, L. M. and Laurent, G., 1999).

4.38.3.4 Odorant Familiarity and Meaning

In thalamocortical sensory systems, individual neuron receptive fields and cortical maps are shaped by experience. Familiar or learned, important stimuli have enhanced representations at the single cell and circuit level, while less familiar or unimportant stimuli have reduced representations. Where it has been examined, these learned changes in cortical sensory representations involve modifications of intracortical association fiber connectivity, potentially including both excitatory and inhibitory synapses, and are mediated by phenomena such as long-term potentiation and long-term depression. The synaptic and local circuit plasticity induced by experience can lead to changes in sensory acuity (perceptual learning) as well as memory of the learned stimuli (associative learning). Experience

also appears to be important in creating synthetic receptive fields, for example in higher-order inferotemporal visual cortex.

Experience also shapes olfactory cortical circuit function (Wilson, D. A. *et al.*, 2004). As noted above, simple odor exposure can result in cortical afferent synaptic depression and cortical odor adaptation. However, several forms of experience-dependent plasticity contributing to odor discrimination and odor memory have also been described in the piriform cortex. This plasticity includes synaptic and circuit changes necessary to synthesize multiple odor features into unique objects distinct from those components as a process of perceptual learning, as well as circuit and membrane biophysical changes important for associative memory of learned odors and the rules involved in learning new odors.

As noted above, familiar odors are more easily identified and discriminated from similar odors than are novel odors (Wilson, D. A. and Stevenson, R. J., 2003). This experience-induced increase in olfactory acuity may be due in part to changes in feature encoding by olfactory bulb circuitry (Fletcher, M. L. and Wilson, D. A., 2003), but also appears to be critically dependent on changes within olfactory cortex. For example, single units in the anterior piriform cortex are unable to discriminate between single odorants and binary mixtures made of those components as determined with a simple habituation/cross-habituation paradigm. Thus, exposure to a novel binary mixture for 10 s is sufficient to cause adaptation of anterior piriform cortical neuron responses to that mixture and causes cross-adaptation to the components of that mixture (Wilson, D. A., 2003). This suggests that these neurons do not discriminate between this novel (never smelled by the animal before) mixture and its components. However, simply extending the duration of exposure to the mixture to 50 s is sufficient to reduce cross-adaptation between the mixture and its components, suggesting that as the mixture becomes more familiar, it becomes more distinctive from similar odors. Olfactory bulb mitral/tufted cells do not appear to be capable of discriminating mixtures from their components in similar conditions. This supports the hypothesis that mitral/tufted cells encode for odorant features, rather than odors as a whole. These cells will respond to any odorant containing a particular feature, and adaptation to that feature will reduce responsiveness to all odors sharing it.

The familiarization effect on cortical odorant discrimination appears to involve plasticity within cortical circuits as noted above in the discussion of content-addressable memory. Application of the muscarinic acetylcholine receptor antagonist scopolamine directly onto the anterior piriform cortex during initial odorant exposure prevents experience-dependent enhancement in cortical odor discrimination (Wilson, D. A. and Stevenson, R. J., 2003). Cholinergic input to the piriform cortex comes primarily from the horizontal limb of the diagonal band and has been shown to modulate both synaptic transmission of piriform cortical associative fiber synapses and plasticity of those synapses. This selective modulation of association fiber pathways might be expected to strongly influence the content-addressable memory function hypothesized to be involved in odor representations, thus impairing odor recognition and discrimination (Hasselmo, M. E. and Barkai, E., 1995).

In addition to perceptual learning, odor experience can also result in associative memories wherein odors acquire predictive value or meaning. Associative olfactory conditioning modifies c-fos expression and 2-deoxyglucose uptake in piriform cortex in response to the conditioned odor, with differential effects on anterior and posterior regions (Datiche, F. *et al.*, 2001; Roth, T. L. and Sullivan, R. M., 2005). Associative conditioning also modifies the effectiveness of olfactory bulb electrically evoked responses in the piriform cortex, again most prominently in the posterior regions. Using high-speed voltage-sensitive dye imaging across a wide region of the piriform cortex, Litaudon P. *et al* (1997) reported that the most significant changes in piriform cortical responsiveness to olfactory bulb input following conditioning were in the longer-latency components of the evoked response, suggesting a primary effect on association fiber synapses. These results further argue that cortical representations of familiar odorants, stored by changes in association connections, may include nonolfactory components.

In fact, activity of neurons in both the piriform cortex and orbitofrontal cortex is influenced by a variety of nonolfactory stimuli in awake animals, including visuospatial or expectancy cues in a well-learned odor discrimination task. Schoenbaum and colleagues (Schoenbaum, G. and Eichenbaum, H., 1995) found no significant difference between piriform cortical neuron single-unit activity and orbitofrontal cortical neuron activity in an odor learning task, with cells in both areas responding to such apparently nonolfactory phases of the task as approach to the odor sampling port and water reward consumption.

In a series of well-designed experiments, Barkai and colleagues have found that the piriform cortex is also modified by odor rule learning in a form of metaplasticity (Saar, D. and Barkai, E., 2003). Rats trained in a series of simple odor discrimination tasks (go, no-go discrimination) dramatically improve their acquisition over repeated odor pairs. For example, if training on an odor A versus odor B task is followed by similar C versus D and then E versus F discriminations, acquisition on the E versus F or subsequent pairings can often occur on a single trial. This has been described as odor set learning, odor rule learning, or learning to learn. Barkai has found that such odor rule learning is associated with heightened excitability of piriform cortical (Saar, D. and Barkai, E., 2003) and hippocampal neurons, as well as changes in dendritic spine number on piriform cortical pyramidal cell dendrites. The membrane excitability changes in piriform cortex are acetylcholine dependent and work through cholinergic reduction of a K-mediated after-hyperpolarization (Saar, D. and Barkai, E., 2003). This enhanced excitability and connectivity may facilitate learning of subsequent odor pairs, as the change would be expected to be a whole-cell phenomenon and thus not odor specific.

4.38.3.5 Nonolfactory Context

As noted above, activity of olfactory cortical neurons is modulated by a variety of nonolfactory stimuli. This modulation could reflect a direct multisensory input to olfactory cortex. For example, the orbitofrontal cortex receives strong input from gustatory and orosensory areas (Rolls, E. T., 2004), and the piriform cortex receives strong input from the multisensory entorhinal cortex (Neville, K. R. and Haberly, L., 2004). The orbitofrontal and piriform cortices are also reciprocally interconnected; thus, there are multiple opportunities for multisensory convergence in either structure. In addition, nonolfactory modulation of olfactory cortical activity could reflect input from nonsensory-specific areas responsive to changes in arousal or behavioral state. For example, the olfactory system is richly innervated by noradrenergic fibers from the nucleus locus coeruleus. Activation of the locus coeruleus can modify piriform cortical single-unit excitability and activity phase relationship to the respiratory cycle (Bouret, S. and Sara, S. J., 2002), either through direct modulation of cortical synaptic physiology or through modulation of olfactory bulb afferent activity (Jiang, M. *et al.*, 1996). Similarly, cholinergic input to the olfactory cortex can modulate piriform cortical synaptic physiology. Both of these systems have direct effects on cortical pyramidal cells, as well as modulatory effects on association fiber synaptic function. They can also both modulate synaptic plasticity in the piriform cortex as noted above, as well as olfactory bulb local circuits (Sullivan, R. M. and Wilson, D. A., 1994).

Modulatory inputs such as from the locus coeruleus and horizontal limb of the diagonal band can signal changes in arousal and internal behavioral state. In doing so, they can differentially influence response properties of olfactory cortical circuits depending on context and expectations. For example, the response seen in the olfactory bulb and piriform cortex as an animal performs a well-learned task of approaching an odor port may reflect either a nonspecific change in cortical arousal and attention signaled by the locus coeruleus or cholinergic inputs. Alternatively, it may reflect other, more specific top-down activation, for example from the entorhinal and higher cortex (Kay, L. M. *et al.*, 1996). Dissecting the differential roles of these two forces will be an important future avenue of research for understanding the effects of context and expectancy in cortical odor processing.

4.38.4 Summary of Olfactory Cortical Information Processing and Unresolved Issues

4.38.4.1 Odor Discrimination

There is increasing evidence that odor discrimination, identification, and adaptation all require olfactory cortical involvement. In humans, lesions of temporal lobe structures that include olfactory cortex, diseases that affect temporal lobe cortical memory areas, and some developmental disorders have all been shown to impair odor identification and discrimination in the absence of impairment of odor detection thresholds (Wilson, D. A. and Stevenson, R. J., 2003). The thesis presented here and elsewhere (Haberly, L. B., 2001; Wilson, D. A. and Stevenson, R. J., 2003) is that olfactory cortex synthesizes odorant features extracted at the periphery and refined by the olfactory bulb into unique perceptual odor objects. This synthesis is an active process involving synaptic plasticity and memory of familiar input patterns. Experience with complex odors results in plasticity of intracortical association fiber synapses within the olfactory cortex, leading to the formation of a content-addressable memory for that odor amongst an ensemble of activated cortical neurons. Subsequent

activation of the cortical circuit with the same, or similar input, reactivates the complete ensemble, leading to odor recognition. As two similar inputs are repeatedly, separately activated, they may come to diverge, enhancing odor discrimination. Thus, experience with odors and the resulting cortical plasticity enhances odor perceptual acuity (olfactory perceptual learning). These general mechanisms are hypothesized to be similar to those involved in visual object recognition and the emergence of visual object receptive fields in inferotemporal cortex. Further examination of odor quality coding in the olfactory cortex, using multiple single-unit ensemble recording, is clearly warranted. In addition, it is now clear that odor quality discriminations can be made within a single sniff in both humans and rodents. A closer analysis of the temporal dimensions of odor quality coding in olfactory cortex should also prove fruitful.

Odor objects may be multimodal, including for example gustatory or other integral components. The influence of stimulus color on odor perception (Gottfried, J. A. and Dolan, R. J., 2003) and the inclusion of gustatory descriptors for purely olfactory stimuli (Stevenson, R. J. *et al.*, 1995) are good examples of this process. The multimodal inputs to olfactory cortex, combined with the synthetic processing just summarized, could easily contribute to this multimodal perception. In fact, associative experience with odors and tastes can facilitate the merger of their perceptual properties.

As in other sensory systems, olfaction may include specialist subregions for specific classes of odorants or odor functions. The orbitofrontal cortex, for example, while heavily interconnected with the piriform cortex, may be particularly important for food odors and other hedonically charged odorants. The different subregions of the piriform cortex may also have specialized roles in olfaction, with for example the posterior piriform more involved in higher-order or multimodal odor representations, though this is a topic in need of further research. In fact, the sensory physiology of large regions of olfactory cortex have not been examined at all.

Finally, it must be emphasized that odorant molecular structure is not synonymous with odor quality percept. Expectations, past experience, internal state, and stimulus intensity can all affect how a given inhaled molecular stimulus is perceived. A major point of this review, and new human imaging evidence (DeAraujo, I. E. *et al.*, 2005), suggests that the transform from molecular features to perceptual object is a cortical event.

4.38.4.2 Sensory Gating

Sensory gating takes several forms including modulation of sensation and perception due to changes in arousal, recent stimulus exposure, and selective attention. Olfactory cortex appears to play a major role in the first two sensory gating phenomena, and may be expected to also be involved in the latter. Spontaneous alternation between fast-wave and slow-wave cortical states, roughly comparable to alert and sleep states respectively, produces corresponding shifts in the state of piriform cortical membrane depolarization. Fast-wave cortical states are associated with depolarized piriform cortical neurons and robust responsiveness to odorant stimulation, while slow-wave states are associated with membrane hyperpolarization and reduced sensory responsiveness (Murakami, M. *et al.*, 2005). In this way, the piriform cortex can gate sensory throughput to higher cortical areas based on arousal level. Similarly, the piriform cortex is a critical component of odor habituation. Activity-dependent presynaptic depression of cortical afferents can account for both cortical and simple behavioral adaptation to odors (Best, A. R. and Wilson, D. A., 2004; Best, A. R. *et al.*, 2005). Prevention of cortical short-term adaptation prevents adaptation of simple behavioral responses, demonstrating that adaptation of receptors in the nose cannot account for short-term behavioral habituation.

Cortical mechanisms of selective attention in olfaction have not been examined. A hypothesis is proposed that olfactory cortical feedback to the olfactory bulb granule cell layer may play a role similar to cortical input to the reticular thalamus in other sensory systems (Crick, F., 1984). Another possibility is that short-term cortical adaptation may be reversible, for example through noradrenergic input (Best, A. R. and Wilson, D. A., 2004), thus allowing an arousal or attentional shift to enhance cortical responsiveness to previously adapted odors. This area requires further attention.

4.38.4.3 Background Segmentation

A cortical and perceptual function that merges odor discrimination and sensory gating is figure-ground separation. In the natural world, odorants are invariable experienced against backgrounds, yet the perceived quality of the foreground odorants can remain constant despite background changes. If odor discrimination and identity were dependent solely on identification of

inhaled features, then odorants experienced against backgrounds would change in quality dependent on the identity of the background. Formation of odorant objects in cortical memory, combined with odor-specific cortical adaptation to background odorants, solves the problem of olfactory figure-ground separation. In fact, recent evidence suggests that piriform cortical neurons respond to odorants against a preexisting background odorant as if the background were not present (Kadohisa, M. and Wilson, D. A., 2006). Olfactory bulb mitral/tufted cells, in contrast, respond to the same situation as if a binary mixture of the background and foreground odorants were present (as they are). Thus, cortical plasticity may be critical for this important ability of the olfactory system to deal with variation in stimulus complexity and analysis of olfactory scenes.

4.38.4.4 Corticobulbar Feedback and Laterality

As in all sensory systems, the olfactory system includes a rich feedback circuitry. In thalamocortical sensory systems, cortical feedback plays an important role in experience and expectation modulation of sensory acuity and sensitivity, as well as selective attention. In olfaction, the olfactory bulb receives strong input from all olfactory cortical structures, and olfactory cortical structures are strongly interconnected and receive descending input from higher-order cortex (Neville, K. R. and Haberly, L. B., 2003). These feedback pathways are activated by past experience and expectancy and may shape odor sensitivity and acuity. This is another area in need of future research.

Similarly, many sensory and higher-order systems express some lateralization of function. The olfactory cortex includes extensive commissural connectivity, and piriform cortical neurons are differentially sensitive to unilateral and bilateral odorant stimulation. Human imaging work suggests there may be some lateralization of function in olfaction (Zatorre, R. J. *et al*., 1992), though this needs to be further examined. The causes and consequences of lateralized cortical function in olfaction should be examined.

In summary, as in all other sensory systems, olfactory cortical structures underlie the critical transition from peripheral analytical processing to synthetic, global processing that leads to the rich perceptual experience that defines the sense of smell. The unique nature of the stimulus in olfaction, however, creates unique problems for processing this information. Though substantial progress has been made in the past 10 years toward understanding the role of olfactory cortex in smell, the field is poised to make major strides by the time this volume is revised.

Glossary

associative memory In this context, the term refers to a type of neural network in which associations between different elements of a stimulus are stored by strengthening connections between these elements. The most important feature of an associative memory is that it will restore a previously stored pattern when presented with an incomplete or distorted version of this pattern.

attractor In dynamical systems analysis, an attractor is any state of a system in which it will remain if otherwise undisturbed. The attractor of a simple pendulum is the vertical position; adding magnets or other disturbances to the system may move the attractor to a new position, or generate additional attractors. Attractors need not be single points; cyclic attractors are common.

Hebbian learning A type of plasticity (learning) rule in which interactions between simultaneously active elements, such as neurons, are strengthened incrementally.

molecular receptive range Equivalent to receptive field for different chemical ligands. In the olfactory system, a neuron's molecular receptive range describes the ensemble of chemicals to which it is responsive.

olfactory bulb Cortical telencephalic structure receiving direct afferent input from olfactory sensory neurons located in the nasal cavity, as well as efferent input from multiple regions of the brain.

signal-to-noise ratio Engineering term quantifying the proportion of the signal of interest (signal) in the total information stream that is transmitted (signal + noise). Low signal-to-noise ratios render it difficult to detect or interpret the signal, as it is buried in noise.

4.39.1 Introduction

In natural environments, airborne chemical stimuli are distributed unpredictably in time and space, and odorants from innumerable sources intermix freely. The olfactory system must be able to detect potential signals of interest within these chemically noisy environments, correctly extract these signals from a complex and changing odor background to form stimulus representations, compare these constructed representations to those of previously experienced odors, differentiate relevant from irrelevant stimuli, and cue an appropriate response. Many of the neural circuit elements comprising the olfactory system have been proposed to contribute to these processes in particular ways; in particular, multiple feedback and feed-forward interactions among olfactory structures, as well as between olfactory and nonolfactory areas, are thought to contribute to the filtering and construction of olfactory representations. Computational models of olfactory processing have been increasingly utilized to describe and interpret these complex and interrelated phenomena.

Primary olfactory sensory neurons (OSNs) number in the millions in rodents. Their axons are highly convergent, targeting specific, discrete neuropilar

synaptic regions within the input layer of the olfactory bulb called glomeruli. In hamsters, for example, between 1300 and 4700 OSNs presumably expressing the same odorant receptor complement converge upon each glomerulus (Schoenfeld, T. A. and Knott, T. K., 2004). These large populations of redundant OSNs and their correspondingly high convergence ratios have been proposed to yield advantages such as improved stimulus sensitivity, an improved signal-to-noise ratio, and an increased range of tuning to different odorant concentrations (van Drongelen, W. *et al*., 1978; Duchamp-Viret, P. *et al*, 1989; Meisami, E., 1989; Cleland, T. A. and Linster, C., 1999). The molecular receptive ranges, or chemical receptive fields, of these odorant receptors overlap substantially, such that the identity of odorants is not associated with the activation of a specific receptor, but rather is represented by a distributed, combinatorial code (Adrian, E. D., 1953; Moulton, D. G., 1967; Stewart, W. B. *et al*., 1979; Kauer, J. S., 1991), now recognized as a pattern of activation across many receptors. Owing to the specific convergence of OSN axons, these odor-specific activity patterns can be most clearly observed in imaging studies of olfactory bulb glomeruli (Friedrich, R. W. and Korsching, S. I., 1997; Rubin, B. D. and Katz, L. C., 1999; Meister, M. and Bonhoeffer, T., 2001; Wachowiak, M. *et al*., 2002). These overlapping representations underlie two critical properties of the olfactory system that a labeled-line solution would not. First, the number of unique odor representations is not limited to the number of different receptor types (roughly 1000 in mice) (Mombaerts, P., 1996), but can be estimated as m^n, where n denotes the number of receptor types and m denotes the number of recognizable states that each sensor can assume, ultimately limited by the signal-to-noise ratio of the system. Even if only two receptor states, active and inactive, are recognized, this enables roughly 2^{1000} potential odor stimuli to be discriminated in mice. Second, the fact that structurally and perceptually similar odorant molecules will activate correspondingly overlapping sets of olfactory receptors (Linster, C. *et al*., 2001; Cleland, T. A., *et al*., 2002; Linster, C. *et al*., 2002) establishes a basis for the recognition of stimulus similarity in the olfactory system. This is a prerequisite for basic postsensory cognitive processes such as generalization (Shepard, R. N. and Chang, J. J., 1963; Shepard, R. N., 1987; Cleland, T. A. *et al*., 2002) and a tolerance for variance among repeated stimulus samples that a labeled-line system would have no clear means of generating.

Distributed patterns of activity in response to chemical stimuli are transmitted to the olfactory bulb via OSN axons that terminate in the glomeruli of its input layer. The olfactory bulb is believed to filter and transform these incoming sensory data, performing normalization, contrast enhancement, and similar operations before conveying the processed olfactory information to several different secondary olfactory structures via mitral cell axon collaterals (Cleland, T. A. and Linster, C., 2003). Notably, the bulb constitutes the last common stage at which olfactory sensory representations can be processed before the signal diverges dramatically into these multiple secondary structures. It is clear from recent investigations that the perceptual qualities of odorants can be predicted, to a limited degree, from the patterns of activation that they evoke at the olfactory bulb input layer (Linster, C. and Hasselmo, M. E., 1999; Linster, C. *et al*., 2001; Cleland, T. A. *et al*., 2002; Linster, C. *et al*., 2002). However, several aspects of odor perception, for example, changes in perception and discrimination capacity due to odor intensity or prior experience, cannot be predicted solely by this first-order representation as reflected in glomerular activation patterns. Furthermore, the olfactory bulb receives substantial centrifugal projections from both cortical and neuromodulatory centers, and its activity is strongly regulated by learning and experience. It is therefore safe to assume that the olfactory bulb plays an important role in processing incoming sensory information. Indeed, many models of olfactory bulb signal processing have been developed, which are grouped here into studies of (1) filtering and contrast enhancement, (2) mechanisms underlying oscillations and spike synchronization, and (3) odor segmentation and associative memory function. In addition, a number of detailed biophysical models of bulbar neurons have been constructed, in many cases, to address how their intrinsic properties underlie and interact with network properties.

4.39.2 Filtering and Contrast Enhancement

The high convergence ratio between OSNs expressing a particular odorant receptor and their target glomeruli in the olfactory bulb (Figure 1(a)) is believed to improve the signal-to-noise ratio during odorant detection (van Drongelen, W. *et al*., 1978), potentially overcoming the limiting noise inherent in

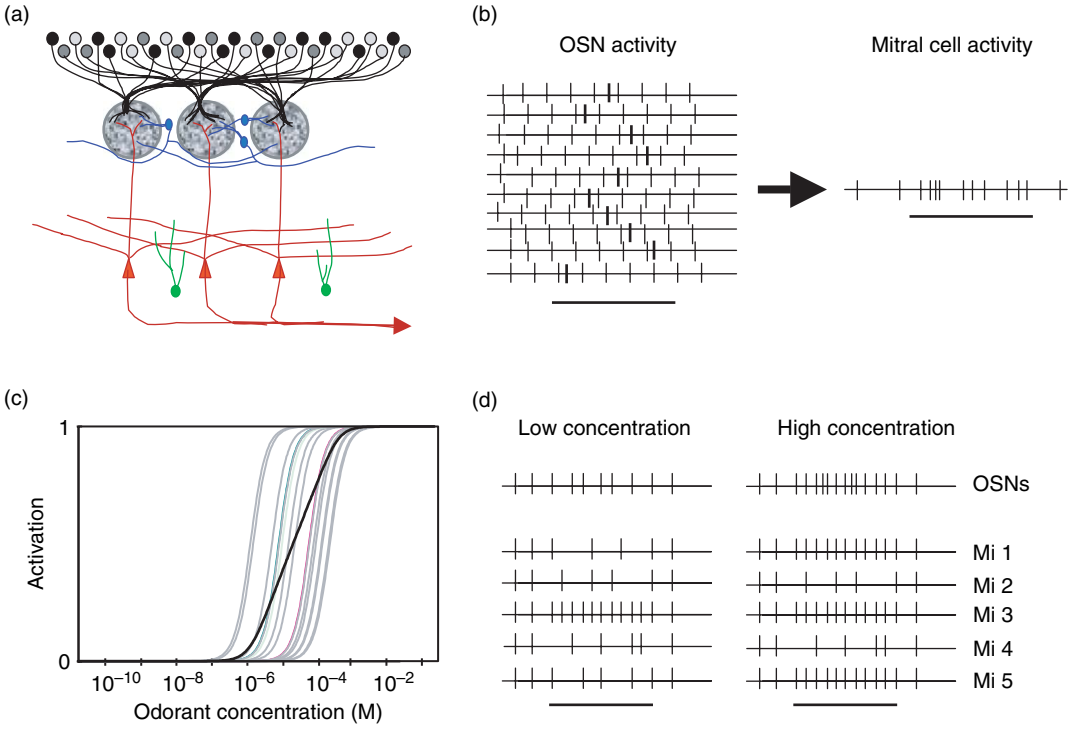

Figure 1 Glomerular computations and convergence. (a) Simplified structure of the olfactory bulb as represented in most computational models. Large populations of olfactory sensory neurons (OSNs) expressing the same receptor (particular shades of gray) converge onto common glomeruli in the olfactory bulb, within which they synapse onto the dendrites of periglomerular (blue) and mitral (red) cells. Mitral cells also excite granule cells (green) via their lateral dendrites, and granule cells in turn inhibit mitral cells; functionally, this mediates lateral inhibition between mitral cells. Periglomerular cells are primarily associated with one or a small number of glomeruli and project axons to a few other glomeruli; these have also been suggested to mediate lateral inhibition between mitral cells. A number of other cell types have also been characterized in the bulb, such as short-axon and tufted cells that are rarely included in computational models; furthermore, established heterogeneity within the cell types modeled has usually been neglected. (b) The high convergence of OSN axons onto mitral cells within each glomerulus significantly improves the signal-to-noise ratio in mitral cells as compared with OSNs. Even if a weak odorant stimulus were to evoke only a single additional spike in each OSN above its basal rate of spiking (OSN activity; bold lines), this high convergence ratio can generate a robust odor responses in a postsynaptic mitral cell (Mitral cell activity), hence enabling mitral cells to reliably represent odor stimuli at lower concentrations than can OSNs (van Drongelen, W. *et al.*, 1978). Horizontal bars depict the time of odorant presentation. (c) While OSN concentration–activation curves are steep, enabling accurate representations of ligand–receptor binding over a range of roughly one log unit concentration, the considerably broader curves observed in glomeruli can be explained if the convergent OSN population is nonuniform in spare receptor capacity or other determinants of intracellular gain (Cleland, T. A. and Linster, C., 1999). If OSNs with identical odorant selectivity but exhibiting different functional spare receptor capacities (gray sigmoids) project onto a single glomerulus, the summed concentration–activation curve of that glomerulus can span several log units of concentration (black sigmoid). (d) Frequency-to-spatial transformation by local glomerular circuits would activate different populations of mitral cells within each glomerulus as a function of the average firing rate of the convergent OSNs (Anton, P. S. *et al.*, 1991). Low concentration odorants (left panel) evoke weak activity in a given receptor-specific OSN subpopulation, generating increased activity in only one mitral cell. In contrast, a high concentration odor stimulus (right panel) evokes greater activity in the OSN population and hence generates measurable excitatory responses in three mitral cells. Horizontal bars depict the time of odorant presentation.

the transduction mechanisms of individual OSNs (Lowe, G. and Gold, G. H., 1995). In principle, this property improves the coding capacity of the olfactory system, increasing the number of different odor-specific patterns that can be discriminated, as well as improving the maximum reliable sensitivity of the system (Figure 1(b)). Another modeling study has suggested that this same property can be employed to increase the range of odor ligand concentrations that can be represented by olfactory bulb glomeruli without saturation (Figure 1(c)) (Cleland, T. A. and Linster, C., 1999). This hypothesis provides a possible

answer to the conundrum of how collective concentration–response curves measured by glomerular imaging can be substantially broader than those measured in individual OSN recordings (Friedrich, R. W. and Korsching, S. I., 1997; Bozza, T. *et al.*, 2002), enabling preservation of the ratios of activation levels among glomeruli across broader concentration ranges and hence potentially facilitating the recognition of odor quality across changes in concentration. Another approach has been suggested by Anton P. S. *et al.* (1991). Noting that the activity of each glomerulus is sampled and conveyed centrally by a number of mitral cells (on the order of 50 in hamsters) (Schoenfeld, T. A. and Knott, T. K., 2004), and that mitral cell firing frequencies do not scale monotonically with concentration as do those of OSNs, these authors proposed that the synaptic circuitry within each glomerulus could compute a frequency-to-spatial transformation on the incoming information. That is, the number of responding mitral cells within a glomerulus, but not their firing rate, would depend on the firing rates of the sensory neurons projecting to that glomerulus in response to odor stimulation (Figure 1(d)).

Contrast enhancement is a common property of sensory systems that narrows, or sharpens, sensory representations by specifically inhibiting neurons on the periphery of the representation, hence enhancing the contrast between signal and background. A number of computational models have investigated the contrast enhancement potential of olfactory bulb circuitry (Figure 2(a)), most of which, by analogy with the retina, have investigated the potential role of lateral inhibitory projections. Classically, bulb models have emphasized lateral inhibition mediated by mitral cell lateral dendrites (Rall, W. and Shepherd, G. M., 1968; Shepherd, G. M. and Brayton, R. K., 1979; Schild, D., 1988; Urban, N. N., 2002; Davison, A. P. *et al.*, 2003). These lateral dendrites form reciprocal synapses with inhibitory granule cell spines in the external plexiform layer of the bulb, forming a network through which mitral cells inhibit one another as well as themselves (Isaacson, J. S. and Strowbridge, B. W., 1998), although the region receiving this inhibition is not clearly localized (Luo, M. and Katz, L. C., 2001; Debarbieux, F. *et al.*, 2003; Djurisic, M. *et al.*, 2004). Subsequent models proposed that contrast enhancement was instead mediated by lateral inhibition mediated by the relatively superficial periglomerular (PG) cells (Linster, C. and Gervais, R., 1996; Linster, C. and Hasselmo, M., 1997) (Figures 1(a) and 2(b)). This hypothesis offered the substantial advantage that lateral inhibition could be delivered onto mitral cells in the glomerular region of their apical dendrites, a location better capable of preventing spike initiation in these cells. In a model based on this hypothesis, Linster C. and Hasselmo M. (1997) further showed that if the activation of PG cells is modulated by cholinergic inputs from the horizontal limb of the diagonal band, a relatively stable number of active mitral cells can be maintained independent of the intensity of olfactory input or the set of OSNs activated by the odorant. In this model, granule cells served instead to modulate the gain of mitral cell activity and were necessary in order to obtain stable average firing rates. Indeed, subsequent studies have shown that PG cells are appropriately modulated by acetylcholine (Castillo, P. E. *et al.*, 1999), and some of the behavioral predictions from these models have been tested in rats (Linster, C. and Cleland, T. A., 2002; Linster, C. *et al.*, 2003; Mandairon, N. *et al.*, 2006).

Contrast enhancement, the effects of which have been observed in the olfactory bulb (Yokoi, M. *et al.*, 1995), can be functionally defined as a process of competition between neurons proportional to the similarity of the information that they mediate. Simplified models of the olfactory system, based on one-dimensional odor subspaces, have been able to implement contrast enhancement using lateral inhibition (Linster, C. and Gervais, R., 1996; Linster, C. and Hasselmo, M., 1997; Linster, C. and Smith, B. H., 1997; Linster, C. and Hasselmo, M., 1999; Linster, C. and Cleland, T. A., 2001; Cleland, T. A. and Linster, C., 2002) and have been effective at interpreting behavioral and physiological data derived from single monotonically varying odorant series (Yokoi, M. *et al.*, 1995; Linster, C. and Hasselmo, M. E., 1999; Cleland, T. A. *et al.*, 2002; Cleland, T. A. and Narla, V. A., 2003). However, to escape this limitation and model more realistic, high-dimensional odor spaces (Hudson, R., 1999; Korsching, S. I., 2001; Alkasab, T. K. *et al.*, 2002), subsequent models have relied upon networks constructed so that the strength of PG-mediated inhibition is effectively proportional to receptive field similarity rather than the physical proximity of glomeruli. Networks based on this assumption have been shown to best reproduce calcium imaging data obtained from honeybee OSNs and projection neurons (analogous to mitral cells), while networks based on decremental lateral inhibition performed comparably to networks based on random inhibitory projections (Linster, C. *et al.*, 2005). Another such model has successfully reproduced mixture processing properties

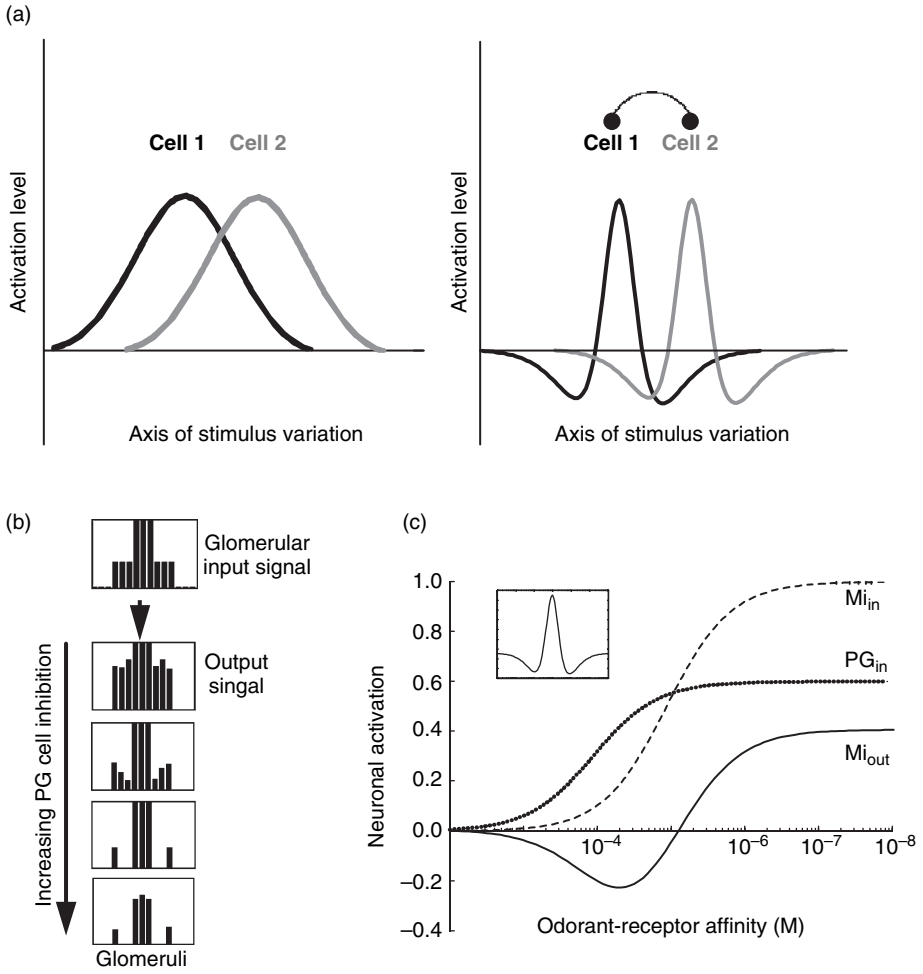

Figure 2 Contrast enhancement. (a) Contrast enhancement is a phenomenon observed in most sensory systems by which marginally activated neurons are excluded from a stimulus-specific ensemble by inhibition, hence sharpening the sensory representation and differentiating it from other, similar representations. In the absence of contrast enhancement, the tuning curves of cells 1 and 2 substantially overlap (left panel). If contrast enhancement is enabled, e.g., by the addition of lateral inhibition such that each cell inhibits the other, the two cells both become more narrowly tuned, and their receptive fields may no longer overlap (right panel). (b) Computational models of the olfactory bulb have proposed that inhibitory periglomerular (PG) cells could mediate contrast enhancement in the glomerular layer of the olfactory bulb. In these models, PG cells receive direct sensory input within a given glomerulus and inhibit mitral cells in neighboring glomeruli via axonal projections (Figure 1(a)). If an odor stimulus activates a range of neighboring glomeruli (Glomerular input signal), increasing the level of PG cell-mediated inhibition would lead to concomitantly sharpened representations among mitral cells, the output layer of the olfactory bulb. With strong contrast enhancement, only the most strongly activated mitral cells are activated, while weakly activated mitral cells are inhibited (Linster, C. and Gervais, R., 1996; Linster, C. and Hasselmo, M. E., 1997). (c) Nontopographical contrast enhancement based on local glomerular computations. In this model, contrast enhancement is generated within the stimulus–response profile of each individual glomerulus, resulting in sharpening of the odor-evoked representation across the glomerular layer. Within each glomerulus, mitral (Mi_{in}) and periglomerular (PG_{in}) cells have the same tuning curves but different response properties, and both receive parallel input from olfactory sensory neurons (OSNs). Mitral cell output (Mi_{out}) is additionally shaped by PG-mediated dendrodendritic inhibition, such that only the most strongly excited mitral cells are activated, while more weakly excited mitral cells exhibit net inhibitory responses (Cleland, T. A. and Sethupathy, P., 2006). The shape of the Mi_{out} curve generates the familiar on-center/inhibitory-surround function of contrast enhancement (inset).
(b) Reproduced from Linster, C. and Gervais, R. 1996. Investigation of the role of interneurons and their modulation by centrifugal fibers in a neural model of the olfactory bulb. J. Comput. Neurosci. 3(3), 225–246, with permission from springer.

measured in rats (Wiltrout, C. *et al.*, 2003; Linster, C. and Cleland, T. A., 2004). Finally, nontopographical models take an entirely different approach to olfactory contrast enhancement, relying solely on intraglomerular computations and broad feedback inhibition to effect contrast enhancement via a 'winner-take-most' algorithm (Figure 2(c)) (Cleland, T. A. and Sethupathy, P., 2006; Cleland, T. A. *et al.*, 2007). This approach does not rely on odorant feature similarities being embedded into bulbar odor maps *a priori*, as it is independent of the physical location of glomeruli and of specific lateral inhibitory projections. Rather, the maps of stimulus feature similarity that underlie contrast enhancement are naturally inherited from the cross-activation patterns of OSNs by odorants.

4.39.3 Mechanisms Underlying Oscillations and Spike Synchronization

While recent models have begun to favor glomerular layer mechanisms for contrast enhancement, granule cell activity also clearly shapes mitral cell response patterns, and hence the presumptive odor representations that emerge from the olfactory bulb. Specifically, several computational models of the olfactory bulb have suggested that the temporal pattern of spiking among mitral cells may play a role in odor representation (Schild, D., 1988; Meredith, M., 1992; White, J. *et al.*, 1992; 1998; White, J. and Kauer, J. S., 2001). While it is clear that temporal response patterns in mitral cells do change as a function of odor identity (Figure 3(a)), there is as yet no broadly accepted theory of how these response patterns may contribute to the representation of odorant stimuli.

One of the most widely studied features of olfactory bulb processing has been the dynamic oscillatory activity patterns observed in the bulb in response to odor stimulation. Models of these phenomena have traditionally studied these responses as coupled oscillators, attributing the dynamics to reciprocal feedback interactions between mitral cell secondary dendrites and granule cells (Figure 3(b)) (Freeman, W. J., 1979; 1987; Li, Z. and Hopfield, J. J., 1989; Grobler, T. and Erdi, P., 1991; Erdi, P. *et al.*, 1993; Freeman, W. J., 1994; Ermentrout, G. B. and Kleinfeld, D., 2001). Some researchers have proposed that odor quality may be represented in dynamic attractors formed in the olfactory bulb (Freeman, W. J., 1979; 1987; Li, Z. and Hopfield, J. J., 1989; Erdi, P. *et al.*, 1993; Freeman, W. J., 1994; Fukai, T., 1996; Hoshino, O.

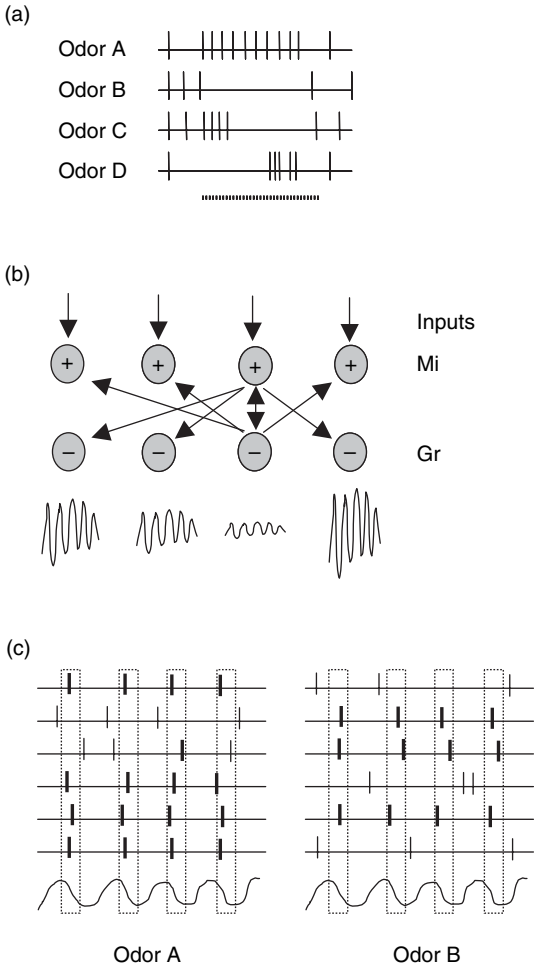

Figure 3 Oscillations and synchrony. (a) Any given mitral cell in the olfactory bulb may respond to different odorant stimuli (A, B, C, and D) with a variety of temporally complex spike patterns including interwoven excitatory and inhibitory phases. It has been proposed that these temporal patterns may contribute to odor representations in the vertebrate olfactory bulb and the analogous insect antennal lobe (Laurent, G., 1999; Laurent, G. *et al.*, 2001). Horizontal bar depicts the time of odorant presentation. (b) The reciprocal synaptic interactions between mitral (Mi) and granule (Gr) cells have often been simulated as a system of coupled oscillators driven by external inputs. In such models, variance of stimulus amplitudes across these inputs generates a map of field oscillations with variable amplitudes and fixed phase lags across the olfactory bulb. For clarity, the output from only a single column is depicted. (c) Field oscillatory dynamics are believed to reflect and/or influence spike timing in mitral cells, potentially resulting in odor-specific populations of mitral cells based on spike synchrony rather than overall activity. While the overall activity patterns evoked by odors A and B are very similar, selection for spikes relatively synchronized with one another and with the oscillatory field potential reveals two clearly odor-specific subpopulations (bold spikes within dotted boxes).

et al., 1998; Breakspear, M., 2001). However, it is increasingly clear that the dynamics of the olfactory bulb are tightly coupled with those of the piriform cortex, and that both depend on mutual feedback between the two structures (Gray, C. M. and Skinner, J. E., 1988; Neville, K. R. and Haberly, L. B., 2003; Martin, C. *et al.*, 2004); combined bulb–cortex models have suggested possible roles for these interactions (Fukai, T., 1996; Li, Z. and Hertz, J., 2000). Other aspects of piriform cortical dynamics have also been modeled (Wilson, M. and Bower, J. M., 1992; Liljenstrom, H. and Hasselmo, M. E., 1995; Claverol, E. T. *et al.*, 2002; Xu, D. and Principe, J. C., 2004), albeit with less focus on their functional role (but see Granger, R. and Lynch, G., 1991).

Recently, models of these field oscillatory properties have begun to emphasize their relationship to the regulation of spike timing in mitral cells (Davison, A. P. *et al.*, 2003; Margrie, T. W. and Schaefer, A. T., 2003), suggesting that patterns of spike synchronization among mitral cells responding to the same sensory input are important contributors to the odorant representation at this level (Figure 3(c)). This phenomenon has been extensively modeled in the insect antennal lobe, a functionally comparable analog of the olfactory bulb. In these models, the regulation of spike synchronization among secondary neurons can mediate stimulus salience and contrast enhancement between similar odorants (Linster, C. and Cleland, T. A., 2001; Cleland, T. A. and Linster, C., 2002) and can dramatically influence the readout of information at the next level of processing (Sivan, E. and Kopell, N., 2004).

4.39.4 Odor Segmentation and Associative Memory Function

Odor segmentation is the general term for the problem of how the olfactory system is able to segregate and identify different odorants that are encountered simultaneously. As most odors comprise multiple separate odorant molecules, it is far from clear how the olfactory system can parse the multitude of odorant stimuli present at any given time and attribute each to appropriately separate sources. One approach has been to hypothesize that odors emitted from different sources can be segregated by OB circuitry based on their differential fluctuations in time (Fort, J. C. and Rospars, J. P., 1992; Hendin, O. *et al.*, 1998; Hopfield, J. J., 1999). Odor segmentation could thereafter be performed in the OB using source-separation algorithms dependent upon associative memory function. Generally, such models hypothesize that associative memories for patterns of olfactory bulb activity evoked by known odorants become embedded in bulbar circuitry and can then be used to recognize these patterns when they recur, even in degraded form. Specifically, a model by Hendin O. *et al.* (1998) illustrates how, if the glomerular layer feeds into a mitral–granule cell layer for which appropriate dynamics for an associative memory function have been implemented, each odor can be separately represented in successive inhalation cycles when multiple (known) odors are presented at the same time.

Olfactory associative memory functions have been more commonly attributed to the piriform cortex, one of the targets of mitral cell axons projecting from the olfactory bulb (Figure 4). Specifically, the piriform cortex has been proposed to mediate the associative memory functions necessary for odor-context learning (Haberly, L. B. and Bower, J. M., 1989; Hasselmo, M. E. *et al.*, 1990; Haberly, L. B., 2001) and hierarchical clustering (Ambros-Ingerson, J. *et al.*, 1990). Indeed, the extensive intrinsic feedback network in this cortex and its integration with afferent inputs closely resembles the structure of traditional theoretical associative memory networks as first described by Marr D. (1971). Several laboratories have constructed models of piriform cortex implementing these associative memory functions (Haberly, L. B. and Bower, J. M., 1989; Ambros-Ingerson, J. *et al.*, 1990; Hasselmo *et al.*, 1990; Barkai, E. and Hasselmo, M. E., 1994; Hasselmo, M. E. *et al.*, 1997) as well as exploring the role of cholinergic modulation in their regulation (Hasselmo, M. E. *et al.*, 1990; 1997; Patil, M. M. and Hasselmo, M. E., 1999; Linster, C. and Hasselmo, M. E., 2001; Linster, C. *et al.*, 2003).

4.39.5 Detailed Biophysical Models of OB Neurons

Most models of the olfactory system to date have emphasized network-level interactions and the properties of olfactory bulb and piriform cortical circuitry, using simplified cell models conducive to these larger-scale simulations. However, several relatively detailed biophysical models of olfactory neurons – particularly OSNs and mitral cells – have also been constructed. Several detailed OSN models have illustrated how ligand–receptor binding and nonlinear transduction processes can underlie several experimentally observed response properties of these cells (Malaka, R. *et al.*, 1995; Rospars, J. P. *et al.*, 1996;

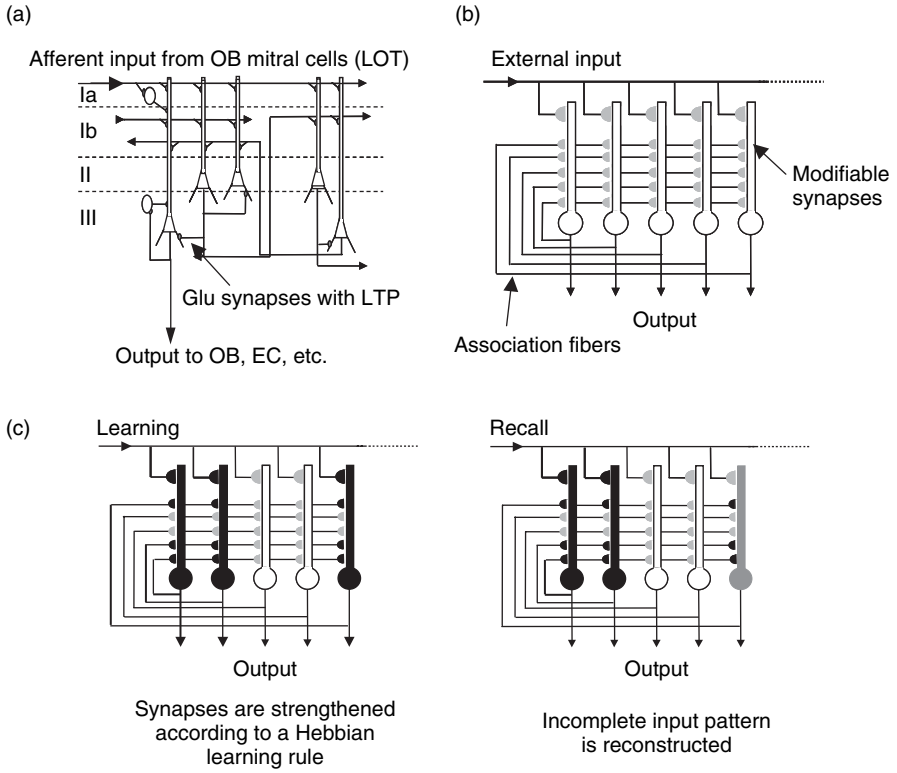

Figure 4 Associative memory function in olfactory cortex. (a) Piriform cortex (PC) exhibits the fundamental anatomical features necessary for the implementation of associative memory: extrinsic input from the olfactory bulb (OB) to each pyramidal cell via the lateral olfactory tract (LOT) and extensive intrinsic excitatory connections among pyramidal cells. These intrinsic associative connections are subject to synaptic plasticity, also crucial for associative memory function, and exhibit long-term potentiation (LTP). Additionally, several classes of local inhibitory interneurons have been described in the piriform cortex. Piriform pyramidal neurons project back to the OB, as well as to other structures such as the entorhinal cortex (EC). (b) Schematic representation of an associative memory network. The critical features are (1) external inputs to associative neurons, (2) all-to-all excitatory connections among these neurons, and (3) a learning rule that modifies the strengths of these connections when external inputs are being learned by the network. (c) Learning and recall in an associative memory network. Learning (left panel): An olfactory stimulus activates a subset of pyramidal cells (three dark cells) via distributed afferent projections from the OB to the PC. During learning, excitatory synaptic connections between pyramidal cells activated by that odorant are strengthened via a Hebbian plasticity rule (dark semicircles denote strengthened synapses). Recall (right panel): After learning of a pattern, if a noisy or degraded example of that pattern is presented to the system, the stored odorant pattern can be reconstructed due to the previously strengthened connections. Dark semicircles denote strengthened synapses. Owing to the previously strengthened synapses, activation of the two dark cells secondarily activates a third cell (gray), reconstructing the previously learned pattern.

Vermeulen, A. *et al.*, 1996; 1997; Kaissling, K. E., 1998; Lansky, P. and Rospars, J. P., 1998; Vermeulen, A. and Rospars, J. P., 1998; Cleland, T. A. and Linster, C., 1999; Rospars, J. P. *et al.*, 2000; Kaissling, K. E., 2001; Kaissling, K. E. and Rospars, J. P., 2004). Compartmental models of mitral cells have been used to elucidate intrinsic cellular phenomena, such as the localization of spike initiation in mitral cells (Shen, G. Y. *et al.*, 1999; Chen, W. R. *et al.*, 2002), or long-term potentiation at the OSN-mitral synapse (Ennis, M. *et al.*, 1998). Other compartmental models have focused on bridging the gap between cellular and systems properties in both vertebrate and insect systems (Bhalla, U. S. and Bower, J. M., 1993; Davison, A. P. *et al.*, 2000; Bazhenov, M. *et al.*, 2001; Davison, A. P. *et al.*, 2003; Cleland, T. A. and Sethupathy, P., 2006; Rubin, D. B. and Cleland, T. A., 2006; Cleland, T. A. *et al.*, 2007).

4.39.6 Conclusions

Computational models have an established and growing role within systems neuroscience. As our

understanding of neural processing and interactions becomes more sophisticated, computer models of these systems are increasingly necessary in order to understand and interpret experimental results. Models serve as proofs of concept, tests of sufficiency, and as quantitative embodiments of working hypotheses. In the olfactory system in particular, computational modeling will no doubt be essential to understanding the integration of the many factors influencing the construction and transformation of odor representations.

Glossary

glomeruli Ball-like regions in which homologous olfactory receptor neurons synapse with second-order neurons in the olfactory bulb.
neuropil A dense network of neural and glial processes.
combinatorial coding The sensory processing of odorant chemicals by the binding of their multiple chemical features to multiple odorant receptors.
2-deoxyglucose A glucose analog that is incompletely metabolized in cells and that can be used for mapping neural activity.
hydrophobic A property that describes the degree of resistance of a molecule to mix with water.
tuning Describes the relationship between systematic changes in the physical properties of sensory stimuli and the level of neural response in a sensory system.
aliphatic Possessing a nonaromatic hydrocarbon structure.
enantiomers Molecules that are non-superimposable mirror images of one another.

4.40.1 Introduction

Buck L. B. and Axel R. (1991) reported the discovery of rat odorant receptor genes and began a series of studies that clarified the foundation of odor perception. Most olfactory sensory neurons in the nose appear to express only one of these genes, and while homologous sensory neurons expressing the same odorant receptor gene are distributed in fairly broad zones stretching from anterior to posterior within the main olfactory epithelium (Ressler, K. J. *et al.*, 1993), they converge in their projections to the brain and connect to a small number of glomeruli in the main olfactory bulb (Vassar, R. *et al.*, 1994). Glomeruli are roughly spherical masses of neuropil that contain synapses between sensory neuron axons and dendrites of projection neurons and interneurons. The typical projection from homologous sensory neurons involves one glomerulus or small grouping of glomeruli on the lateral aspect and a similar projection on the medial aspect of the bulb (Mombaerts, P. *et al.*, 1996). All sensory neuron synapses in a glomerulus appear to be from cells expressing the same receptor (Treloar, H. B. *et al.*, 2002).

This orderly projection pattern, which is consistent across different animals, suggests that one can get a read-out of odorant receptor activation from the pattern of odorant-evoked activity in the glomerular layer. This prediction now has been tested using a variety of activity-mapping methods. In our own work, we use the uptake of radiolabeled 2-deoxyglucose (2DG) as a metabolic marker, as this is the only method currently able to give a quantitative measure of relative activity throughout the entire structure at a spatial resolution sufficient to detect activity in a single glomerulus.

4.40.2 Combinatorial Coding

Even pure, simple odorant molecules tend to activate multiple locations in the olfactory bulb, and each area

of activation tends to encompass many glomeruli (Johnson, B. A. *et al.*, 1998; 1999). These findings suggest that odor perception probably arises from a combination of activated odorant receptors. Similar conclusions have come from the study of sensory neurons expressing distinct receptor genes (Malnic, B. *et al.*, 1999), from the study of glomerular responses using other methods (Uchida, N. *et al.*, 2000; Wachowiak, M. and Cohen, L. B., 2001), and from the study of action potentials in mitral cells (Imamura, K. *et al.*, 1992). Indeed, there are far more unique odor perceptions than there are odorant receptors, a situation that logically necessitates a combinatorial code.

4.40.3 Molecular Feature Detection

Most receptors appear not to interact with the entirety of their ligand molecules. Rather, parts of the ligand molecule can be modified with minimal impact on receptor binding and activation, while other parts of the ligand molecule are more critical. Indeed, one can think of receptors as detectors of these critical molecular features. We have designed a large number of experiments using sets of odorants differing systematically in chemical structure to explore the detection of molecular features by odorant receptors. In one experiment, each of two ethyl esters stimulated 2DG uptake in a part of the bulb that was not activated by either of two isoamyl esters (Johnson, B. A. *et al.*, 1998). Conversely, both isoamyl esters activated a location not stimulated by either ethyl ester. The activity patterns were consistent with the recognition of the ethyl and isoamyl groups as distinct features by different glomerular modules in the bulb. All four esters stimulated a distinct, overlapping module, consistent with the overall similarity in their core structure.

We tested a set of five odorants sharing a straight-chained hydrocarbon structure but differing in oxygen-containing functional groups to determine whether functional groups would be recognized as distinct molecular features (Johnson, B. A. and Leon, M., 2000a). While all of these odorants stimulated a cluster of glomeruli in the posterior bulb, consistent with their shared hydrocarbon structure, they activated distinct anterior modules, consistent with the recognition of functional groups as distinct features. When we used carboxylic acid odorants that differed greatly in hydrocarbon structure, anterior clusters of activated glomeruli overlapped, consistent with the shared acid functional group, but the posterior patterns differed greatly, consistent with the recognition of different hydrocarbon structures as distinct features (Johnson, B. A. and Leon, M., 2000b). As we increased our sample of the odorant world to include more and more complex molecules, the data showed that the recognition of functional groups as molecular features is not entirely independent of hydrocarbon structure, but rather, that the two types of features interact to determine which glomeruli are activated (Johnson, B. A. *et al.*, 2005a; 2005b).

4.40.4 Chemotopic Progressions

Chemotopy refers to any systematic spatial representation of odorant chemistry. We have been particularly interested in determining whether the olfactory system uses this kind of spatial organization in odor coding. Indeed, glomeruli of related specificity are arrayed systematically within response modules. Uptake of 2DG in a medial, acid-sensitive glomerular module shifted ventrally with increasing carbon number in a series of straight-chained carboxylic acids (Johnson, B. A. *et al.*, 1999). In the corresponding lateral module, uptake shifted both rostrally and ventrally. Separate responses in the posterior, lateral, and the medial bulb also shifted ventrally with increasing carbon number. By using a series of carboxylic acids of the same carbon number, but with different hydrocarbon structures, we found that the ventral shift in the medial acid-responsive module appeared to be due specifically to changes in molecular length (Johnson, B. A. and Leon, M., 2000b). More recently, we found ventral progressions of activity with increasing odorant carbon number using aldehydes, esters, acetates, primary and secondary alcohols, ketones, and alkanes in a number of different glomerular regions, suggesting that such chemotopic progressions represent a fundamental organizational principle in the olfactory system (Johnson, B. A. *et al.*, 2004; Ho *et al.*, 2006) (Figure 1).

Why are the chemotopic progressions with increasing carbon number always in the ventral direction? One possibility is that the chemotopic progressions are related to the spatial distributions of the odorants themselves across the olfactory epithelium. Mozell and co-workers have shown that odorants partition across the epithelium chromatographically (Mozell, M. M., 1964; Hornung, D. E. and Mozell, M. M., 1977; Mozell, M. M. *et al.*, 1987). Molecules that are more water soluble (hydrophilic)

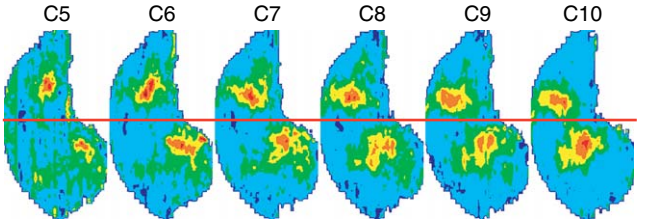

Figure 1 Chemotopic progression of glomerular responses in the ventral and rostral direction with increasing carbon number in straight-chained aldehydes. The maps are in a ventral-centered orientation such that the red line indicates the ventral extremity of the bulb. In each map, rostral is to the left. Warmer colors indicate higher uptake of the metabolic marker, 2-deoxyglucose.

absorb more readily into the olfactory mucosa, which would prevent them from reaching the more peripheral and ventral parts of the rat epithelium (Schoenfeld, T. A. and Knott, T. K., 2004). The less water-soluble (more hydrophobic) odorant molecules would be freer to distribute across the epithelium to reach the more peripheral and ventral zones. Longer odorants within any homologous series of straight-chained chemicals would be more hydrophobic and therefore would be expected to reach the peripheral and ventral epithelium. Because the more peripheral and ventral regions of the epithelium project to more ventral bulbar targets (Schoenfeld, T. A. *et al.*, 1994), this topography could explain the ventral chemotopic progressions within many glomerular modules in the olfactory bulb (Johnson, B. A. *et al.*, 2004).

Local bulbar anatomy suggests that chemotopic progressions in the glomerular layer might have important functional consequences. Reciprocal synapses between mitral cell projection neurons and inhibitory interneurons in the glomerular layer and in the external plexiform layer are expected to create local lateral inhibitory networks. Strong activity in mitral cells associated with a given glomerulus would likely suppress activity in less strongly stimulated mitral cells associated with neighboring glomeruli (Mori, K. and Shepherd, G. M., 1994; Aungst, J. L. *et al.*, 2003). This pattern of activity would be predicted to tune individual mitral cells to a more narrow range of molecules than would excite individual sensory neurons. Indeed, pharmacological blockade of inhibition in the bulb widens the molecular receptive range of mitral cells (Yokoi, M. *et al.*, 1995). Chemotopic progressions ensure that the glomeruli that are nearest neighbors within a module would have the most similar specificity within a homologous series, thereby ensuring that tuning involves the most similar odorant molecules.

4.40.5 Predictive Value of Activity Maps

The value of any scientific observation is perhaps best judged by whether it allows one to predict the outcome of future experiments. Maps of odorant-evoked 2DG uptake across the glomerular layer of the olfactory bulb have been predictive in two senses: they have predicted aspects of the patterns that would be evoked by previously untested odorants, and they have predicted relative similarities in odors perceived by rats. The original associations between functional group-related molecular features and activity in particular anterior glomerular modules (Johnson, B. A. and Leon, M., 2000a) successfully predicted that other simple aliphatic odorant chemicals possessing the same features would also stimulate those modules (Johnson, B. A. *et al.*, 2002; 2004). Aspects of glomerular activity patterns related to hydrocarbon structure also have had predictive value (Johnson, B. A. *et al.*, 2002). The ventral shifts in activity that we observed with increasing carbon number for aliphatic, oxygen-containing odorants (Johnson, B. A. *et al.*, 1999; 2004) led us to predict that even larger straight-chained molecules might stimulate an extremely ventral portion of the bulb that we had not seen activated previously. We tested this prediction using very long alkanes such as pentadecane, which indeed activated the extreme ventral aspect (Ho *et al.*, 2006).

As part of our exploration of the relationships between odorant chemistry and bulbar activity patterns, we mapped responses to three pairs of odorant enantiomers: carvone, limonene, and terpinen-4-ol. The patterns evoked by the two carvones were more distinct than those for the other two enantiomer pairs (Linster, C. *et al.*, 2001). We therefore predicted that the odors of the carvone enantiomers might be more readily distinguished than those of the limonenes and

terpinen-4-ols. Indeed, a cross-habituation assay revealed that rats spontaneously distinguished the carvones, but treated limonene and terpinen-4-ol enantiomers as being similar in odor (Linster, C. *et al.*, 2001). The quantitative differences in activity patterns across homologous series of acids and alkanes also correlated well with behavioral measures of odor discrimination (Cleland, T. A. *et al.*, 2002; Ho *et al.*, 2006).

4.40.6 Summary

As predicted from the projection patterns of olfactory sensory neurons expressing distinct odorant receptor genes, different odorants generate different spatial activity patterns in the olfactory bulb. Mapping activity patterns in response to odorants differing systematically in structure has shown that receptors likely extract information about odorant chemistry, especially regarding functional groups and hydrocarbon structure. The bulb responses are organized in space according to the relative specificity of the input, such that increasingly long straight-chained odorants optimally stimulate increasingly ventral glomeruli. Finally, the overall pattern of glomerular activation is related to the odor perceived by rats.

Glossary

2-DG labeling A technique used to label active cells. Radioactive 2-DG ([^{14}C]2-deoxyglucose) is injected into the animal. Physiologically active cells accumulate 2-DG because it is taken up as a glucose analogue but accumulates because it cannot be metabolized. Cells that are particularly active accumulate more 2-DG and are therefore apparent in an autoradiograph. For each activity map, a single animal has to be killed.

acetylcholine (ACh) A neurotransmitter. In the insect brain, ACh is the major excitatory transmitter between neurons. The major excitatory neurotransmitter at the insect neuromuscular junction is glutamate.

antennal lobe (AL) The first neuropil in the insect brain to receive olfactory information, comparable to the mammalian olfactory bulb. It is located in the deutocerebrum.

antennal mechanosensory and motor center (AMMC) Neuropil situated in the deutocerebrum dorsally to the insect's AL (also called dorsal lobe). Among others, it receives the axonal terminals of mechanoreceptor cells on the antenna and contains the somata of antennal motor neurons.

antennocerebralis tract (ACT) Axonal tract between the AL and the protocerebrum. There are several ACTs in each brain, traveling in different routes.

arista Feather-like appendix on the *Drosophila* antenna involved in forming a recipient structure for vibrations. Sensory sensilla are also located on the arista.

associative memory See *Pavlovian conditioning*.

biogenic amines Neurotransmitters that have an amine group, comprising catecholamines (epinephrine, dopamine, and norepinephrine = noradrenalin) and indoles (tryptophan and serotonin). Many of them are involved in modulatory functions in the insect brain.

blocking Term from learning psychology. Assume that an association of a stimulus A with a reward is learned, and subsequently stimulus A is trained together with a stimulus B (i.e., AB). When learning about B is reduced (even though B was trained as a compound in AB), then A has blocked B. Blocking is generally explained using cognitive concepts of attention or expectation.

boutons Presynaptic structures in neurons.

calcium-sensitive dye A dye that changes its light properties as a function of calcium concentration. Most are fluorescent substances. These dyes are often used as reporter molecules for neural activity. Examples are calcium green, FURA, and fluo-3.

calyx, calyces See *mushroom body*.

cameleon See *G-CaMP*.

classical conditioning See *Pavlovian conditioning*.

combinatorial code A coding logic whereby information is not stored in a single channel (see *labeled line*), but rather across several channels. Different combinations of active channels indicate different information. Take, for example, 10 channels: simultaneous activity in channels 1, 3, and 5 constitutes a different combination (and thus coded information) than activity in channels 1, 3, and 6. A combinatorial code greatly amplifies the coding capacity of a given number of channels.

conditioned stimulus (CS) See *Pavlovian conditioning*.

deutocerebrum See *supraesophageal ganglia*.

differential training In Pavlovian conditioning, when two stimuli are used as CS, with one being rewarded and the other not, or one being punished and the other not.

dorsal lobe (DL) Neuropil in the deutocerebrum located dorsally to the AL. Contains the AMMC.

G-CaMP A genetically engineered fluorescent protein that changes its fluorescent properties with changing Ca^{2+} concentration. G-CaMP can be used to monitor cell activity when it is expressed in a cell. Another such reporter protein is cameleon. The two differ in spectral properties, Ca^{2+} affinity, and binding kinetics.

gamma-aminobutyric acid (GABA) Neurotransmitter that in most cases binds to receptors that have an inhibitory effect on the recipient cell. GABA is the most important inhibitory transmitter in the brain.

glomerulus Named after the spherical arrangement of dense neuropil in the AL which is apparent in microscopic sections, the glomeruli form the functional units within the AL. Generally, they collect all input from a particular type of olfactory sensory neurons (OSNs).

habituation A term from learning psychology. An animal habituates to a repeatedly presented stimulus and ignores its presence. Habituation is different from sensory adaptation or fatigue. Habituation is a nonassociative learning phenomenon: a strong stimulus of a different or even the same modality can instantly dishabituate an animal, showing that sensory information about the stimulus is not reduced.

hemimetabolous insects Insects that go through several developmental stages (instar larvae) that resemble the adult stage. Metamorphosis is gradual, without a pupal stage. For example, cockroaches and locusts. See also *holometabolous insects*.

heterogeneous local neuron (heteroLN) In this chapter, local neurons in the AL that branch in many glomeruli but have a clear polarity in that one or at most a few glomeruli are densely innervated, while most glomeruli are innervated only sparsely.

holometabolous insects Insects that undergo complete developmental metamorphosis, with a larval stage, followed by a pupal stage, followed by the adult. The larva is very different from the adult and generally occupies a different ecological niche. The best-known example is the butterfly, with the caterpillar larva. Bees, flies, and moths are holometabolous.

homogeneous LN In this chapter, local neurons in the AL that branch in many glomeruli without a clear polarity.

ionotropic receptor Ligand-gated ion channels that mediate fast excitatory or inhibitory neurotransmission.

Kenyon cell (KC) Intrinsic cell of the mushroom body in insects, first described by Kenyon F. C. in 1896.

labeled line Coding principle whereby a single channel carries information independently from the activity status of other channels, as opposed to a combinatorial code. In a binary system, four channels can carry 4 bits of information in a labeled line system, while four channels can carry 16 bits of information in a combinatorial code.

latent inhibition Term from learning psychology, which refers to the effect of unreinforced preexposure with a CS that leads to a reduced learning.

local neuron (LN) In this chapter used for neurons that are local to the AL, i.e., their entire branching arbors are confined within the AL.

mating disruption A technique in pest control aimed at modifying pest behavior with semiochemicals. For example, when large quantities of female pheromone are released in the environment, males are less efficient in finding their females, and thus natural mating patterns are disrupted.

metabotropic receptor A type of neurotransmitter receptor that, upon binding with a neurotransmitter, activates an intracellular second messenger cascade (e.g., involving cAMP), as opposed to opening an ion channel.

***molecular receptive range* (MRR)** The chemosensory response properties of a chemoreceptor or of a chemosensory neuron, i.e., the range of molecules for which the receptor is receptive.

multielectrode array A technique to measure many neurons at the same time with multiple electrodes that penetrate the brain. Each electrode can record extracellular activity from one or a few cells in its vicinity. Different cells are sorted by the spike shapes that they produce. Some multielectrode arrays are made of silicon and others of isolated wires.

mushroom body (MB) A structure in the insect protocerebrum. The intrinsic cells of the MBs are the KCs. Their somata and dendrites form the calyx, and their axons form the α-lobe, β-lobe, and

γ-lobe. The name comes from the shape of this structure, reminiscent of a mushroom.

negative patterning Term from learning psychology. In negative patterning, two single stimuli are reinforced, but their compound is not (i.e., A^+, B^+, AB^-). Therefore, while A and B each have predictive power for the reward, their mixture has not. Solving a negative patterning problem requires configural association and cannot be solved with elemental learning alone (see also *positive patterning*).

neuropeptides Short-chain peptides in the brain, e.g., enkephalins and endorphins, that function as intercellular messengers. There is a large variety of peptides, which are often species-specific and have dedicated receptors in the recipient cells. Peptides are often released as cotransmitters and modulate the affect of a transmitter at the recipient cell.

neuropil A dense feltwork of neural processes (dendrites, axons, and neurites) and glial processes. Generally, in insects, the cell bodies of the brain are arranged peripherally and the neuropil areas contain only very few cell bodies.

nitric oxide (NO) A gas that is also produced by cells and functions as a messenger between cells.

olfactory binding protein (OBP) A protein in the sensillar lymph of olfactory sensilla that participates in the olfactory process. Its function is as yet unclear. Among the current hypotheses for its function are that it might help dissolve the odors in the aqueous lymph or that might remove odor from the receptor after it has interacted.

olfactory bulb (OB) The vertebrate counterpart to the insect AL.

olfactory receptor (OR) A seven-transmembrane protein in OSNs that interacts with the odorant molecules and initiates the intracellular transduction cascade.

olfactory sensilla In insects, ORs are housed in sensilla, which are cuticular structures with pores on the insect's surface. Sensilla vary greatly in shape and size, including hair-like protrusions, flat plates, or funnel-like indentations.

olfactory sensory neuron (OSN) The primary olfactory neurons. OSNs express ORs on their dendrites and express the transduction cascade. Upon contact with the appropriate stimulus, they send action potentials (APs) along their axons into the ALs in the brain. Often referred to as OR neurons, or sometimes even receptors. The latter term is now avoided in order to prevent confusion with the OR proteins.

Pavlovian conditioning Also called classical conditioning. A neutral stimulus (the CS) is repeatedly presented immediately before a reward (or punishment, the unconditioned stimulus, US), so that the CS has predictive value for the US. The animal learns the coincidence of the two events forming an associative memory. Before learning, only the US leads to a response (the unconditioned response, UR). After learning, also the CS leads to a response (the conditioned response, CR). In Pavlov's famous dog experiment, the bell is the CS, the food is the US, and salivation is the UR and the CR. In bee PER (proboscis extension reflex) conditioning, the CS is an odor stimulus, the US is nectar (or sugar water), and the CR is the extension of the bee's proboscis (PER).

pheromone Chemical substance used for communication within a species. Sexual pheromones are used for sexual attraction and/or arousal. Other pheromones include alarm pheromones and trail pheromones in ants. The first pheromone to be isolated biochemically was Bombycol, the sexual pheromone of the moth *Bombix mori*, found by Butenand A. in the 1950s. Chemical messengers are also used between species: those advantageous for the receiver are called kairomones, those advantageous for the emitter are called allomones, and those that benefit both are called synomones.

Picrotoxin A pharmacological substance that blocks many ionotropic chloride channels. Generally, these channels are GABAergic receptors, and Picrotoxin is used to block these receptors.

positive patterning Term from learning psychology. In positive patterning, two single stimuli are not reinforced, but their compound is (i.e., A^-, B^-, AB^+). Therefore, neither A alone nor B alone has predictive power for the reward, but only their mixture. Unlike negative patterning, positive patterning can be solved with elemental learning mechanisms, without the need of configural association.

proboscis extension reflex (PER) The response to an appetitive stimulus. For example, when a honeybee is presented a drop of sugar water, it reflexively extends its proboscis.

projection neuron (PN) In this chapter, a neuron that projects out from the AL.

protocerebrum See *supraesophageal ganglia*.

subesophageal ganglia (SEG) The insect brain consists of the supraesophageal ganglia, which are

joined to the SEG by two connectives. Together, these structures form a ring around the esophagus. The SEG consists of a fusion of several pairs of ganglia. Often referred to as SOG (based on British spelling: suboesophageal ganglia).

supraesophageal ganglia The insect brain consists of a fusion of several ganglia arranged above the esophagus. The anterior part is the protocerebrum, which contains the MBs, the central complex, and the optic lobes. The posterior part contains the deutocerebrum (AL and DL) and the smaller tritocerebrum.

synaptopHluorin An artificially created fluorescent protein that changes its fluorescent properties with changing pH value and is localized in synaptic vesicles. synaptopHluorin can be used to monitor synaptic transmitter release when it is expressed in a cell.

tritocerebrum See *supraesophageal ganglia*.

unconditioned stimulus (US) See *Pavlovian conditioning*.

voltage-sensitive dye (VSD) A dye that intercalates into cell membranes and changes its light properties with the membrane potential. VSDs can be used to measure membrane potentials of cells with light.

α-lobe See *mushroom body*.

γ-lobe See *mushroom body*.

4.41.1 Introduction

In order to understand how the insect brain processes information, it is necessary to understand the anatomy and physiology of the neurons involved in this task. In a very simplified picture, information by olfactory sensory neurons (OSNs) is processed first in the antennal lobes (ALs), and then in the mushroom bodies (MBs) and the lateral protocerebrums (LPs). In this chapter, these three areas are treated sequentially, and information about morphology, physiology, and function is collected for each. At the end, olfactory behavior in insects is discussed.

It is useful to separate at least three transformation steps involved in olfactory coding, which correspond to transformations between four multidimensional spaces. First is the external multidimensional space, that is, the odor world, which has dimensionality and axes defined by the chemical and physical properties of the odorant molecules. Some of these axes are easy to define, like carbon chain length for simple hydrocarbons or electronegativity for functional group residues. Molecular resonance frequencies, which are exploited in spectroscopic techniques, also define a classification system (Turin, L., 1996). However, any arrangement of molecules in such a multidimensional space is a matter of definition, rather than reflecting a naturally dictated order. The second one is a biologically defined multidimensional space, where each dimension is given by the response properties of OSNs. The mapping of the physical–chemical space onto the receptive space is the first step in olfactory coding. It consists of interactions with olfactory binding proteins (OBPs) and other extracellular proteins, the olfactory receptor proteins (ORs), and intracellular second messenger pathways. The third multidimensional space consists of activity patterns across neurons in the AL and its several additional transformations along processing steps within the brain, which are mediated by the neural networks within the AL or the MBs. These steps enhance information that is relevant to the animal and filter less-relevant content, increase signal over noise, optimize sensitivity, and/or reformat the coding scheme in a way that makes it easier and more reliable to decode, so that information is better stored and/or extracted. This information consists of any combination of (1) the identity of an odor stimulus (an identification task), (2) its concentration (a measurement along a continuous variable), (3) the identity of odor components in a mixture (an analytical task), (4) the identity of a combination of odor components in a mixture (a synthetic task), and (5) the analysis of odor plume sequences (a temporal task). Finally, the last and biologically most relevant olfactory space is the perceptual space, which results in behavioral decisions. Thus, the first, physical odor space (of unknown order and dimensionality) is mapped onto a primary, receptive odor space (with a clearly defined dimensionality dictated by the number of ORs), then transformed into several physiological spaces (which might work sequentially, in parallel, or both), which in turn is the basis for the perceptual odor space.

4.41.2 Cellular Organization of the Antennal Lobe

The AL is the first neuropil in the insect brain that processes olfactory information. It is evolutionarily shared within the protostome clade and present in all insects, with the exception of some anosmic species where it was secondarily lost (Strausfeld, N. J. and Hildebrand, J. G., 1999). Both in its structure and in its function, it is remarkably similar and analogous to the vertebrate OB, although it evolved independently (Strausfeld, N. J. and Hildebrand, J. G., 1999). There is one major difference in design, which reflects a structural difference between the nervous tissue in insects and that in vertebrates: In the insect brain, most neuronal cell bodies lie at the periphery of the brain, and they extend neurites that branch within the brain, forming axons and dendrites. In the AL, neurons have their somata in cell clusters around the AL itself and branch in olfactory glomeruli, which are the interaction sites of OSNs, local neurons (LNs), projection neurons (PNs), and others. Very few synapses are found outside the glomerulus (Gascuel, J. and Masson, C., 1991; Boeckh, J. and Tolbert, L. P., 1993). In vertebrates, the bulb is organized in a more columnar fashion, with cellular interactions within several layers beneath the olfactory glomeruli, and LN networks separated in these layers. To a first approximation, therefore, the insect glomerulus is functionally comparable to a vertebrate glomerular column, rather than to the glomerulus alone. However, this analogy remains an approximation, because the OB is not columnar beneath the glomerulus. For example, mitral cell somata can be displaced laterally with respect to the glomerulus innervated by their dendritic tuft (Shepherd, G. M. and Greer, C. A., 1998).

The considerable similarity to vertebrates should not prevent us to recognize that within insects the diversity of AL organization is large (Schachtner, J. *et al.*, 2005). Insects have an evolutionary history of over 400 000 000 years, and most modern insect orders were already present since 250 000 000 years, which allows for considerable divergent evolution (Grimaldi, D. A. and Engel, M. S., 2004). As a minor example, cell somata are arranged in distinct clusters around the AL in most insects, but the distribution of cell bodies for functionally different neurons (e.g., LNs vs. PNs) is not conserved among species. In the following, I will mention the different organizational principles found in those species that have been studied in more detail than others. For hemimetabolous insects, most results are from locusts, among which *Locusta migratoria* (Orthoptera), and cockroaches, notably *Periplaneta americana* (Blattodea). In holometabolous insects, the best studied are the fruit fly, *Drosophila melanogaster* (Diptera), a variety of moths, in particular *Manduca sexta* (Lepidoptera), and the honeybee, *Apis mellifera* (Hymenoptera). Where useful, I will follow the sequence bee, moth, fly, cockroach, and locust for clarity.

4.41.2.1 Antennal Lobe Glomeruli

A striking similarity across animal phyla is the glomerular organization of the primary neuropil of the olfactory system, be it the OB of vertebrates or the AL in insects (Hildebrand, J. G. and Shepherd, G. M., 1997). This unique structural principle might reflect a basic property of olfactory coding, possibly because there is no physical property common to all odors that can be mapped in a small number of dimensions. Such an oligodimensional representation is possible for spatial position of light stimuli, or frequency coding for sounds. Color coding, however, does not make use of the unidimensional property of photon wavelength but rather creates artificial dimensions with different color-sensitive photoreceptors and subsequent color-opponency channels, which can be very few (two such channels in humans and honeybees). Olfaction is intrinsically multidimensional, and a glomerular morphology may be a structural organization that helps convert a multidimensional set of inputs into a topological map. The resulting glomerular organizing principle would be functionally dictated. Alternatively, a glomerular organization may just be the most parsimonious organization of many coalescing axons with equal response properties, resulting from the convergence of OSNs onto one point in the central nervous system.

In insects, the number, shape, and arrangement of glomeruli vary greatly among species: an adult *Drosophila* fruit fly has less than 50 glomeruli (Stocker, R. F., 1994; Laissue, P. P. *et al.*, 1999), a moth (*Manduca*) has ~60 (Sanes, J. R. and Hildebrand, J. G., 1976b; Rospars, J. P. and Hildebrand, J. G., 1992), a cockroach has ~125 (Ernst, K. D. *et al.*, 1977), a worker honeybee has ~160 (Flanagan, D. and Mercer, A. R., 1989a; Galizia, C. G. *et al.*, 1999b), and some ant species have over 200 (Rospars, J. P., 1988) or even 400 glomeruli (Ozaki, M., personal communication). In many species, glomeruli are arranged around a central area of the AL, the coarse neuropil, while in

others, generally smaller animals, glomeruli are more densely packed, filling most of the AL. Glomeruli are the functional units within the AL, but nevertheless, there is a substructure within them. In bees the outer cap and the core of each glomerulus receive input from different neuron types: OSNs innervate the outer cap, and within this cap, the antenna is topologically arranged. Many LNs innervate only the core of those glomeruli that they sparsely innervate. In honeybees, serotonergic neurons innervate only the cap and dopaminergic neurons only the core. Consequently, each glomerulus is concentrically organized, and the cap may serve a function different from the core. Furthermore, in immunostainings for protein kinase C (PKC), small circular regions of dense staining are visible within honeybee glomeruli (Müller, U., personal communication; see also Grünbaum, L. and Müller, U., 1998). In mass-fills of OSNs similar dense knots can be seen (own observations). Whether these two substructures coincide is not known, and their functional significance, if any, also remains obscure. A subcompartmentalization of glomeruli has been shown for *Drosophila* (Laissue, P. P. *et al.*, 1999) and is also known from vertebrates (Kasowski, H. J. *et al.*, 1999). Morphologically and most likely functionally, there is an inner life to a glomerulus that remains to be elucidated: possibly, glomeruli are not the smallest unit of the olfactory code.

The term glomeruli is also used in locusts, even though their arrangement differs from that in most other species (Ignell, R. *et al.*, 2001). There are about 1000 glomeruli, with each receptor neuron axon innervating several of them, and each projection neuron branching in many of them (Ernst, K. D. *et al.*, 1977; Anton, S. and Hansson, B. S., 1996). It is clear that there is no morphological homology between the locust glomeruli and those of other insects. Nevertheless, anatomically they are dense knots of neuropil and therefore referred to as glomeruli. Furthermore, even if the AL is structured differently, basic mechanisms of olfactory coding may still be the same in locusts and other insects. For example, application of the chloride channel blocker Picrotoxin has similar effects on the temporal response structure in PNs in bees (Stopfer, M. *et al.*, 1997) and in locusts (MacLeod, K. and Laurent, G., 1996). Therefore, a comparative approach, and a thorough comparison of results from all species, is needed.

The most complete ultrastructural analysis of synaptic connections between neurons in the AL has been done in cockroaches. Briefly, almost any possible synaptic contact is realized (Malun, D. 1991a; 1991b; Distler, P. G. and Boeckh, J., 1996; 1997a; Distler, P. G. *et al.*, 1998b). That is, OSNs synapse onto LNs and onto PNs, and their presynaptic terminals themselves receive input from AL neurons. LNs synapse onto OSN terminals, other LNs, and PNs. PNs get input from OSNs and LNs, and they synapse onto other cells in the AL. No synapses from PNs onto OSNs have been found. The presence of LN input to OSNs indicates that the AL network already controls magnitude and maybe timing of afferent input activity, as shown in crustaceans and vertebrates (Wachowiak, M. *et al.*, 2002).

4.41.2.2 Glomerular Atlas of the Antennal Lobe

The low numbers of glomeruli in insects, and their characteristic arrangements and sizes, have allowed mapping them, and creating 3D-Atlases (Rospars, J. P., 1988). Initially, these were morphological descriptions based on serial sections, but in recent years confocal reconstructions of whole ALs have been used. Computer-based atlases are increasingly available over the Internet and can be used for relating findings to identified glomeruli, thus greatly enhancing the comparability of results among research groups. Unfortunately, the electronic format used by different laboratories and for different species still needs unification. The quest for electronic brain atlases in general (Toga, A. W. and Thompson, P. M., 2001) will soon lead to more uniform standards among insect researches, not only for the AL, but also for the entire brain (Rein, K. *et al.*, 2002; Brandt, R. *et al.*, 2005).

The honeybee AL has been mapped, and glomeruli were named according to the antennal tract that innervates them (T1–T4) and a number (i.e., T1-1, T1-2, or T3-33) (Flanagan, D. and Mercer, A. R., 1989a). An electronic version based on confocal sections was published later (Galizia, C. G. *et al.*, 1999b) and is available for download over the Internet (see Relevant Websites section).

Atlases are also available for different moth species (Rospars, J. P. and Hildebrand, J. G., 1992; Berg, B. G. *et al.*, 2002; Huetteroth, W. and Schachtner, J., 2005; Ignell, R. *et al.*, 2005; Masante-Roca, I. *et al.*, 2005; Skiri, H. T. *et al.*, 2005).

The *Drosophila* AL was first mapped based on serial sections (Stocker, R. F. *et al.*, 1990) and later based on confocal sections (Laissue, P. P. *et al.*, 1999). Each of the 43 glomeruli mapped so far is named with a letter or

two indicating the AL area and a number, e.g., DM2 for dorsomedial-2. This atlas is also freely available for downloading (see Relevant Websites section). Glomeruli that are identified later can be easily included into this nomenclature (Couto, A. *et al.*, 2005).

Currently, there is no glomerular atlas for cockroaches. It is unlikely that there will ever be an atlas for locusts, given the ambiguity of glomerular borders and the high number of glomeruli.

4.41.2.3 Sensory Neuron Axons

4.41.2.3.1 Antennal nerves

Chemosensory neurons are present on the surface of many areas of the insect body, including legs, wings, genitalia, and head appendices. All (nonanosmic) insects have olfactory sensilla that contain OSNs on their antennae, and some, notably dipterans, also on the maxillary palps. Structure and function of OSNs and the diversity of olfactory sensilla are treated in other chapters. OSN axons project to the AL via the antennal tract(s). In many species, there is more than one antennal tract. In honeybees, there are four tracts, T1–T4, that innervate different glomeruli (Suzuki, H., 1975). The honeybee T1 and T3 innervate ~70 glomeruli each, and T2 and T4 innervate seven glomeruli each (Arnold, G. *et al.*, 1983; Flanagan, D. and Mercer, A. R., 1989a; Galizia, C. G. *et al.*, 1999b). Since each glomerulus has a distinct functional response spectrum (see below), the antennal tract segregation may have a functional significance. In honeybees, the morphology of the innervating OSN terminals differs between glomeruli innervated by the four antennal tracts (Mobbs, P. G., 1982). Furthermore, this segregation corresponds to distinct groups of PNs that leave the AL following different tracts (see below) (Abel, R. *et al.*, 2001; Kirschner, S. *et al.*, 2006).

Antennal nerves contain other axons too: mechanosensory and gustatory axons from the antenna travel along the AL, bypassing it toward the antennal mechanosensory and motor center (AMMC) in the dorsal lobe (DL) (Suzuki, H., 1975; Gewecke, M., 1979; Mobbs, P. G., 1982; Kloppenburg, P. *et al.*, 1997). In honeybees, these are tracts T5 and T6. Efferent axons for antennal muscles, originating in motor neurons in the DL, use these tracts to enter the antenna. Finally, axons from modulatory neurons, with their unpaired cell bodies in the subesophageal ganglion, also enter the antenna. These neurons most likely use biogenic amines as transmitters. While their function has not yet been elucidated directly, a modulatory effect of biogenic amines on OSNs has been shown (Pophof, B., 2002).

4.41.2.3.2 Olfactory sensory neuron numbers

The number of OSNs differs greatly among species, and within some species among sexes. Male honeybees (drones) have ~300 000 OSNs, while (female) worker bees have ~65 000, the difference being probably due to the male's sensitivity for the queen's sexual pheromone (Esslen, J. and Kaissling, K. E., 1976). In *Manduca*, sexual dimorphism is reflected in OSN response properties, and not their numbers: both males and females have ~300 000 OSNs on each antenna (Sanes, J. R. and Hildebrand, J. G., 1976c; Oland, L. A. and Tolbert, L. P., 1988). *Drosophila* has ~1200 OSNs in both sexes (Stocker, R. F. *et al.*, 1990). Adult cockroaches have ~150 000 OSNs (Ernst, K. D. *et al.*, 1977). As juveniles, cockroaches have less OSNs. As they grow, they increase the number of antennal segments and sensilla with each nymphal instar (Schafer, R. and Sanchez, T. V., 1973). The number of OSNs in locusts is between 50 000 (Ernst, K. D. *et al.*, 1977) and 105 000 (Anton, S. *et al.*, 2002) and also increases over developmental stages (Ochieng, S. A. *et al.*, 1998; Chapman, R. F., 2002).

4.41.2.3.3 Projection of olfactory sensory neurons into the antennal lobe

Generally, one OSN axon innervates a single ipsilateral glomerulus in the AL, where it branches and where it forms many synapses. It is unknown how many synapses a single axon forms within the glomerulus, but given the often extensive branching of these axons, the number is likely to be high. In most cases, branching is strongest in the outermost layer of the innervated glomerulus, but in some species (e.g., cockroaches) or some subpopulations of glomeruli (e.g., T4 in bees), OSN axons invade the entire glomerulus. In bees, there is a concentric topological arrangement of OSN input to glomeruli, with OSNs from the distal antennal segments innervating the outer layer of the glomerulus, and more proximal OSNs occupying more central layers (Pareto, A., 1972). These layers are, however, strongly overlapping and may be dictated by developmental constraints rather than by functional necessity. Antennotopic projections have also been found in *Manduca* (Christensen, T. A. *et al.*, 1995) and *P. americana* (Hösl, M., 1990). Synapses are formed onto both LNs and PNs and are often dyadic, that is, one presynaptic element with two postsynaptic elements,

or even more complex (Malun, D. 1991a; Distler, P. G. and Boeckh, J., 1996; Sun, X.-J. *et al.*, 1997). In flies, most axons innervate a bilateral pair of homologous glomeruli, and OSNs form an axonal commissure between the two ALs (Strausfeld, N. J., 1976; Stocker, R. F., 1994). Each bilaterally innervated glomerulus receives equal input from both antennae (Vosshall, L. B. *et al.*, 2000). Some glomeruli, however, are innervated only unilaterally; in *D. melanogaster*, these are V, VL1, VP1, as well as VP2 and VP3 that collect all input from sensilla located on the *Drosophila* arista (Stocker, R. F. *et al.*, 1983; Stocker, R. F., 2001).

In locusts, most OSN axons innervate several glomeruli ipsilaterally (Ernst, K. D. *et al.*, 1977), but some innervate only one glomerulus (Anton, S. *et al.*, 2002).

4.41.2.3.4 Targeting mechanisms of olfactory sensory neurons

Targeting of OSNs onto glomeruli is best understood in *Drosophila*. After the ORs were characterized (Clyne, P. J. *et al.*, 1999; Gao, Q. and Chess, A., 1999; Vosshall, L. B. *et al.*, 1999), the mapping of their target areas has been intensely pursued (Couto, A. *et al.*, 2005; Fishilevich, E. and Vosshall, L. B., 2005). Indeed, the nomenclature of olfactory glomeruli by spatial location (e.g., DM2 for glomerulus 2 in the dorsomedial area) might eventually be used synonymously with the name of the OR gene expressed in the OSNs innervating it (e.g., dOr22a for DM2). The current rule is that each OSN expresses only one OR and that OSNs expressing the same OR converge on a single glomerulus in each hemisphere (Vosshall, L. B. *et al.*, 2000), but there are exceptions: in transgenic animals, a few axons go astray to other glomeruli (Bhalerao, S. *et al.*, 2003). Some OSNs express more than one OR. For example, dOr22a and dOr22b are coexpressed in ab3a (for antennal basiconic sensillum 3, neuron a), and their axons converge onto glomerulus DM2 in the AL, but dOr22b does not seem to contribute to the olfactory response of those neurons (Dobritsa, A. A. *et al.*, 2003). In pb2a OSNs (palp basiconic type 2, neuron a), receptors dOr33c and dOr85e are coexpressed, and in this case, both contribute to these neurons' molecular response profiles (MRRs) (Goldman, A. L. *et al.*, 2005). Other OSN axon populations innervate two glomeruli even though expressing the same OR. For example, OSNs expressing dOr67d innervate the two glomeruli DA1 and VA6 (Fishilevich, E. and Vosshall, L. B., 2005). An almost complete mapping of dOrs and their target glomeruli is now available for adult *Drosophila* (Couto, A. *et al.*, 2005; Fishilevich, E. and Vosshall, L. B., 2005). From this it is clear that the general rule one OSN – one receptor – one glomerulus is valid in most cases, but not followed strictly, allowing for additional degrees of freedom in functionally organizing chemosensory responses. In addition, most but not all OSNs express an additional OR-like receptor, which is dOr83b in *Drosophila* (Larsson, M. C. *et al.*, 2004), and which has an ortholog receptor in all other insects investigated so far, including mosquitoes, bees, moths, and beetles (Krieger, J. *et al.*, 2003; Pitts, R. J. *et al.*, 2004; Jones, W. D. *et al.*, 2005). OR expression in *Drosophila* OSNs is discussed in more Chapter Phototransduction in Microvillar Photoreceptors of Drosophila and Other Invertebrates.

In mammals, ORs are important for OSN axon targeting to the appropriate glomerulus (Wang, F. *et al.*, 1998; Feinstein, P. and Mombaerts, P., 2004; Feinstein, P. *et al.*, 2004). In insects, the innervated glomerulus is independent of the OR that is expressed (Dobritsa, A. A. *et al.*, 2003). Other factors are required for correct OSN targeting in *Drosophila*, including the Src homology domain 2 (SH2)/SH3 adapter Dock (Ang, L. H. *et al.*, 2003), the serine/threonine kinase Pak (Ang, L. H. *et al.*, 2003), the cell surface proteins *N*-cadherin (Hummel, T. and Zipursky, S. L., 2004), the immunoglobulin Dscam (Hummel, T. *et al.*, 2003), and the POU domain transcriptional factor Acj6 (Komiyama, T. *et al.*, 2004). Many of these factors are only expressed in subpopulations, suggesting some sort of combinatorial mechanism. For example, Dscam disrupts OSN targeting in many OSN axons, but not in those expressing the receptors dOr22a, and only partially in some others (Hummel, T. *et al.*, 2003). All OSNs in the antenna express Acj6, but not all OSNs in the maxillary palps do. Furthermore, precise OSN targeting is not only regulated by intrinsic transcriptional control but also by axon–axon interaction (Komiyama, T. *et al.*, 2004) and interactions with glial cells (Tolbert, L. P. *et al.*, 2004). Glomerular identity appears to be determined before OSN ingrowth, with the participation of PNs forming protoglomeruli (Jefferis, G. *et al.*, 2004).

4.41.2.3.5 Olfactory sensory neuron odor responses

Responses in OSN axons to odorants originate from the response properties of the ORs expressed in that axon, and other interactions at the periphery including OBPs. Response properties measured at the periphery are covered in another chapter.

Functional response properties of olfactory glomeruli have been measured in several species using optical imaging techniques, notably flies (Ng, M. *et al.*, 2002; Fiala, A. *et al.*, 2002; Wang, J. W. *et al.*, 2003), bees (Galizia, C. G. and Menzel, R., 2001; Fiala, A. *et al.*, 2002; Sachse, S. and Galizia, C. G., 2002; 2003), moths (Galizia, C. G. *et al.*, 2000a; Carlsson, M. A. *et al.*, 2002; Skiri, H. T. *et al.*, 2004), and ants (Galizia, C. G. *et al.*, 1999a). In all cases, glomeruli had characteristic odor-response profiles, confirming that a single or at most very few ORs dictate their response properties. Consequently, also in species other than *Drosophila*, OSNs expressing the same OR are likely to converge generally onto a single glomerulus. Additional support comes from the observation that in the recently sequenced genome of the honeybee, *A. mellifera*, the number of OR genes is close to 160 (Robertson, H. M. and Wanner, K. W., 2006). This number matches closely the number of glomeruli found in this species. Thus, molecular and optophysiological data have superseded earlier models of AL innervation based on single-cell electrophysiology that assumed OSNs with equal response profiles to innervate several glomeruli, and each glomerulus to receive input from several OSN types (Boeckh, J. and Tolbert, L. P., 1993). For locusts, where individual OSN axons innervate several glomeruli, no data about OSN targeting are as yet available.

OSNs differ in how broad their response spectrum is. Narrowly tuned OSNs form a labeled line: each OSN responds only to a single substance, and thus when that OSN is active, animals can behave assuming that the substance is in the environment. Such a system is very specialized, and in its extreme form, the number of odors that can be coded corresponds to the number of OSNs with different response profile (which would be ~43 in the adult *Drosophila*). On the other hand, broadly tuned OSNs create a combinatorial code. Each odor activates many OSN types, and each OSN can be activated by many odors. Thus, the information carried by individual glomeruli becomes ambiguous. It is only by analyzing the pattern of active glomeruli that the animal can identify an odor. Experiments show that many OSNs respond to a variety of substances at high concentration but may be exquisitely sensitive to a few molecules at a concentration several orders of magnitude lower (Røstelien, T. *et al.*, 2000; Stensmyr, M. C. *et al.*, 2003; Pelz, D. *et al.*, 2006). Are they highly sensitive labeled lines, or rather units in a combinatorial code? Animals are exposed to odorants over a large range of concentrations in their natural environment. A honeybee, for example, can smell an odor source over large distances (low-concentration task) but also recognize it when sitting on a flower (high-concentration task). The olfactory system should therefore be capable of differentiating, for a given OSN, between the occurrence of a low-concentration best ligand and a high-concentration secondary ligand. This cannot be done on the basis of a single OSN response itself and must be done by a pattern analysis across several OSNs. Even for sexual pheromones, the labeled line at OSN level is converted into a combinatorial system for the next processing step. Pheromones consist of blends of several substances, and extraction of the correct pheromone blend information is done by a combinatorial analysis of the respective glomerular activities (Christensen, T. A. and Hildebrand, J. G., 2002; Shirokova, E. *et al.*, 2005). Some species, such as *Helicoverpa armigera* and *Helicoverpa assulta*, have pheromone blends consisting of the same substances, but in different relative concentrations, so that relative activity becomes important information (Berg, B. G. *et al.*, 2005).

Most OSN responses are temporally structured: some are inhibited by odors and show rebound excitation at the end of the stimulus, some fire for a long time irrespective of stimulus duration, others only fire for a very short time, and stop even if the stimulus continues (de Bruyne, M. *et al.*, 2001). Some but not all of these effects are due to adaptation of the OSNs (tonic versus phasic response properties). The consequence for the central nervous system is that it gets a temporally complex input from the OSNs. This is in addition to the intrinsic temporal complexity that air-borne odors always have (Murlis, J. *et al.*, 1992). The question as to whether these temporal structures are used for odor analysis and whether the periphery rather than the AL network may cause part of the temporal patterns observed within the AL is discussed below.

OSN responses can also be inhibitory. Because the background activity differs among OSN types, an inhibitory ligand might become evident only when an OSN is also activated by another ligand, resulting in nonlinear mixture interactions (de Bruyne, M. *et al.*, 2001).

4.41.2.3.6 Olfactory sensory neuron transmitters

The OSN transmitter is likely to be acetylcholine (ACh), which is the primary excitatory transmitter in the insect brain. The evidence, however, is not

conclusive yet, and mostly based on the detection of the ACh-synthesizing enzyme choline acetyltransferase (ChAT) (Kreissl, S. and Bicker, G., 1989; Bicker, G., 1999a). ACh is present in *Manduca* OSNs (Sanes, J. R. and Hildebrand, J. G., 1976a; Stengl, M. *et al.*, 1990). Pressure application of ACh leads to activity (depolarization and hyperpolarization) in moth AL neurons, mediated by nicotinic receptors (Waldrop, B. and Hildebrand, J. G., 1989). In *Drosophila*, a ChAT/lacZ tranformant labels OSNs (Yasuyama, K. *et al.*, 1995), but immunoreactivity for ACh is low (Yasuyama, K. and Salvaterra, P. M., 1999). In all species studied so far, however, the presence of ACh, ChAT, and α-bungarotoxin binding sites was heterogeneous among glomeruli, leaving the possibility that there might be another, as yet unknown, transmitter (or cotransmitter) in OSNs (Kreissl, S. and Bicker, G., 1989; Homberg, U. *et al.*, 1995; Homberg, U. and Müller, U., 1999) or that glomeruli differ in receptor and/or vesicle density.

In moths, OSN axons contain nitric oxide (NO) synthase and release NO when activated by odors (Gibson, N. J. and Nighorn, A., 2000). NO signaling stimulates glial migration, and blocking NO signaling in development disrupts proper glomerular development in the AL (see Section 4.41.2.7) (Gibson, N. J. *et al.*, 2001). NO is also present in honeybee ALs, but it is unclear whether NO is produced in OSNs or other cells (Hosler, J. S. *et al.*, 2000; Bicker, G., 2001). The NO/cGMP system is involved in olfactory habituation in honeybees (Müller, U. and Hildebrandt, H., 2002), and blocking NO activity in adult honeybees disrupts olfactory discrimination in a similar way as when chloride channels are blocked (Hosler, J. S. *et al.*, 2000). In cockroaches and locusts, NO is not synthesized in OSNs but is synthesized in LNs (Elphick, M. *et al.*, 1995; Seidel, C. and Bicker, G. 1997; Ott, S. R. and Elphick, M. R., 2002).

4.41.2.4 Local Neurons

LNs are defined as neurons whose branching patterns are limited to the AL alone. Their somata are located close to the AL, and their neurites branch among olfactory glomeruli, and within them. Many different morphologies have been described, and a variety of transmitters and expressed peptides are known. Synaptic connections among LNs and with other neurons have been analyzed in few species only. Descriptions from different species vary in approach and technique, making a thorough comparison difficult. It is clear that we are lacking considerable knowledge about LNs in insects.

4.41.2.4.1 Morphology of local neurons

Morphologically, LNs fall into two major classes. One type innervates most if not all glomeruli uniformly. These neurons have been named symmetrical LNs (Matsumoto, S. G. and Hildebrand, J. G., 1981; Ernst, K. D. and Boeckh, J., 1983; Anton, S. and Homberg, U., 1999) or, in bees, homogeneous LNs (homoLNs) (Flanagan, D. and Mercer, A. R., 1989b). Another type innervates only a small number of glomeruli. In bees, these heterogeneous LNs (heteroLNs) have one dominant glomerulus with dense innervation, and several glomeruli with very sparse innervation (Flanagan, D. and Mercer, A. R., 1989b; Sun, X.-J. *et al.*, 1993a). They branch only in the core of the sparsely innervated glomeruli but branch in the core and the outer cap of the densely innervated glomeruli (Fonta, C. *et al.*, 1993; Abel, R. *et al.*, 2001). In moths, all asymmetric neurons described so far innervate a small group of glomeruli sparsely (asymmetric LNs) without a single, dominant glomerulus (Matsumoto, S. G. and Hildebrand, J. G., 1981). Symmetric and asymmetric LNs together account for the vast majority of LNs in the AL, with heteroLNs (asymmetric) dominating in bees (Flanagan, D. and Mercer, A. R., 1989b; Fonta, C. *et al.*, 1993; Sun, X.-J. *et al.*, 1993a), and symmetric LNs dominating in moths (Christensen, T. A. *et al.*, 1993). Other morphological types are LNs that innervate some dorsal glomeruli of the AL and areas of the AMMC (which makes their definition as LNs questionable), so far published for bees (Flanagan, D. and Mercer, A. R., 1989b). A thin connection between the two ALs has been described in bees (Arnold, G. *et al.*, 1985; Mobbs, P. G., 1985), which appears to contain about 30 GABAergic fibers in immunohistochemical sections (Schäfer, S. and Bicker, G., 1986). These neurons are multiglomerular (Fonta, C. *et al.*, 1993) and may be related to bilateral comparisons, regulation, and inhibition of AL activity.

In *Drosophila*, two GAL4 lines that label two distinct sets of LNs have been described. Both consist of homogeneously branching LNs, but density, morphology, and location of branches within glomeruli differ (Ito, K., personal communication). The functional differences in these two lines are also unknown. A third group of LNs is cholinergic and mediates excitatory interactions within the AL (Shang, Y, *et al.*, 2007). LNs that bilaterally connect the two ALs are also found in *Drosophila* and at least

some of them innervate only glomerular subsets and not the entire AL (Stocker, R. F. *et al.*, 1990; Stocker, R. F., 1994).

4.41.2.4.2 Local neuron numbers

Counts of LNs in insects are difficult, and rarely better than a gross estimate. There are up to 4000 LNs in bees (see below), ~360 LNs in moths (*M. sexta*) (Homberg, U. *et al.*, 1988), and ~100 (GABAergic) LNs in *Drosophila* (Ng, M. *et al.*, 2002). The estimates for other species are ~300 LNs both in cockroaches and in locusts (Anton, S. and Homberg, U., 1999).

Honeybees have by far the highest number, with up to 4000 LNs. This count is based on about 7350 neurons in each deutocerebrum, that is, the AL and DL taken together, of which 4750 are directly associated with the AL (Witthöft, W., 1967). The vast majority of these are either LNs or PNs. Assuming 800 PNs (see below), this leaves almost 4000 LNs.

4.41.2.4.3 Transmitters used by local neurons

Most LNs are GABAergic, with GABA-like immunoreactivity shown in bees (Schäfer, S. and Bicker, G., 1986), moths (Hoskins, S. G. *et al.*, 1986), *Drosophila* (Jackson, F. R. *et al.*, 1990; Buchner, E., 1991), cockroaches (Malun, D., 1991b; Distler, P. G. *et al.*, 1998b), and locusts (Leitch, B. and Laurent, G., 1996; Ignell, R. *et al.*, 2001). LNs get synaptic input also from GABAergic LNs. In *Drosophila*, GABAergic LNs expressing the GABA biosynthetic enzyme glutamic acid decarboxylase also express GABA receptors, both metabotropic and ionotropic (Ito, K., personal communication).

In bees, ~750 LNs stain for GABA (Schäfer, S. and Bicker, G., 1986), which forms a rather low proportion of GABAergic interneurons as compared with other insects, where most LNs appear to be GABAergic. Knowledge about LNs that are nonGABAergic is limited, with the exception of a population of about 35 LNs in honeybees that stain for histamine as a transmitter (Bornhauser, B. C. and Meyer, E. P., 1997). Application of histamine blocks activity in the honeybee AL (Sachse, S. and Galizia, C. G., 2002), suggesting that it acts as an inhibitory transmitter. The function of histaminergic LNs with regard to odor coding and processing is still unknown and needs further investigation. Since OSNs in flies express G-protein-coupled glutamate receptors, there probably is a population of glutamatergic LNs that synapse onto (at least some) OSN terminals (Ramaekers, A. *et al.*, 2001).

A pharmacological analysis is difficult in insects, because receptor affinities are not well characterized for most artificial antagonists and agonists. Furthermore, the long evolutionary history of insects results in considerable diversity. For example, the $GABA_A$ antagonist bicucculine modifies AL activity in moths (Christensen, T. A. *et al.*, 1998b), but not in bees, flies (own observations), and locusts (MacLeod, K. and Laurent, G., 1996). The chloride channel blocker Picrotoxin has both a washable and a nonwashable effect in bees (Sachse, S. and Galizia, C. G., 2002), but only a nonwashable effect in moths (Waldrop, B. *et al.*, 1987). The $GABA_B$ blocker 2H-saclofen is effective in moths (Lei, H personal communication), and the $GABA_B$ blocker CGP54626 is effective in fruit flies (Wilson, R. I. and Laurent, G., 2005).

LNs differ in their expression of neuropeptides. The available data show that many, often small populations of LNs, express characteristic peptides, including but by far not limited to allatotropin, allatostatins, tachykinins, FMRFamide, and other RFamide peptides. The patterns of peptide antiserum stainings differ widely among the species (Homberg, U. *et al.*, 1990; Nässel, D. R., 1993; Davis, N. T. *et al.*, 1996; Homberg, U. and Müller, U., 1999; Nässel, D. R., 2000; Homberg, U., 2002; Nassel, D. R. 2002; Schachtner, J. *et al.*, 2004; Iwano, M. and Kanzaki, R., 2005). Some neuropeptides are coexpressed with GABA while others are not. In locusts, locustatachikinin is found in a population of about 20 GABAergic neurons (Ignell, R. *et al.*, 2001). Myotropic neuropeptides of the orcokinin family are found in cockroach and locust LNs, but not in moths, bees, and flies (Hofer, S. *et al.*, 2005).

4.41.2.4.4 Physiology of local neurons

LNs have action potentials (APs) in honeybees (Sun, X.-J. *et al.*, 1993a; Galizia, C. G. and Kimmerle, B., 2004), moths (Christensen, T. A. *et al.*, 1993), flies (Wilson, R. I. *et al.*, 2004), and cockroaches (Ernst, K. D. and Boeckh, J., 1983), but in locusts LNs are nonspiking (Laurent, G. and Davidowitz, H., 1994).

In species where LNs spike, they can be tonically active in the resting animal and increase or decrease their firing upon stimulation with odors. In bees and moths, most intracellular recordings from LNs show multiple spike amplitudes. This might indicate that LNs with complex branching patterns have multiple spike initiation zones or that LNs are electrically coupled. Alternatively, their fine processes might lead to artificial electrical connections created by

the penetrating sharp electrode, in which case multiple spike heights would be an experimental artifact (Galizia, C. G. and Kimmerle, B., 2004). HeteroLNs in honeybees have distinct odor-response profiles comparable to those of uniglomerular PNs. Generally, the odors they respond to correspond to the odors expected from the honeybee functional atlas, that is, LNs respond to those odors associated with its dominant glomerulus, suggesting that their morphologically dominant glomerulus is their input site (Galizia, C. G. and Kimmerle, B., 2004). In contrast, homoLNs studied in *Drosophila* have very broad response profiles, responding to most odors, with activity spread across their entire arborization (Ng, M. *et al.*, 2002; Wilson, R. I. *et al.*, 2004). Furthermore, *Drosophila* is the only species, so far, where both inhibitory and excitatory LNs have been characterized (Shang, Y. *et al.* 2007).

LNs influence the responses in PNs in at least two ways: first, with a very fast inhibition, mediated by GABA acting on ionotropic channels, and second, on a slower timescale, which leads to continuing inhibitions even after stimulus offset (Christensen, T. A. *et al.*, 1998a). Studies with pharmacological antagonists have shown that the fast GABA-mediated currents cause synchrony among PN spikes, and odor-evoked oscillations in the 20–30 Hz range (MacLeod, K. and Laurent, G., 1996). Furthermore, LNs also mediate a disinhibitory connection between OSNs and PNs, which leads to an excitatory response in PNs. In this sequential arrangement OSN–LN–LN–PN, a tonically active LN tonically inhibits a PN; upon OSN activity, another LN becomes active, inhibits this LN, and thereby releases the PN from its inhibition, resulting in PN activity (Av-ron, E. and Rospars, J. P., 1995).

Across insects, the available data are insufficient to draw firm conclusions about LN response profiles. The function that LNs play for olfactory coding is discussed below (Section 4.41.3.2).

4.41.2.5 Projection Neurons

PNs connect the AL to other brain areas. Uniglomerular neurons branch in a single glomerulus within the AL and have axons that lead from the AL to the MBs and to the LP. Multiglomerular neurons branch in several if not all glomeruli and generally have axons that do not innervate the MBs, but a variety of other areas in the protocerebrum, both lateral (close to and overlapping with the LP) and more central (surrounding the α-lobe of the MB). PNs have both input and output synapses within olfactory glomeruli. It is unclear, though, whether all PNs have output synapses within the AL or only some of them.

4.41.2.5.1 Projection neuron morphology and tracts

Nomenclature of PN tracts is inconsistent across insect species, reflecting both their morphological diversity and a lack of knowledge about the homology of the tracts involved. Morphologically, in most species there is a strong antennocerebralis tract (ACT) that travels along the brain midline (mACT (medial ACT) in bees and iACT (inner ACT) in most other species), and a generally smaller tract that travels close to the optic lobes (lACT (lateral ACT) in bees, oACT (outer ACT) in moth, and mACT in flies). In addition, there are several minor tracts that sometimes share parts with the lACT/oACT, and whose axons target different areas (multiglomerular ACTs (mlACTs) in bees and mACTs in most other species). I will therefore present different insects sequentially. Branching patterns of PNs in the MBs and the LP are discussed in their respective sections below.

In bees, uniglomerular PNs form two tracts, the lACT and the mACT (Mobbs, P. G., 1982). The mACT travels along the brain midline toward the MBs where collaterals enter into the MB calyces, and continues to end branching in the LP. PNs in the mACT originate from glomeruli of the T2, T3, or T4 group (Bicker, G. *et al.*, 1993; Abel, R. *et al.*, 2001; Kirschner, S. 2006) and have their somata in the ventrolateral and dorsal soma cluster of the AL (Bicker, G. *et al.*, 1993). The lACT leaves the AL dorsally and then travels on the lateral, or outer side, close to the optic lobes. Collaterals enter the LP, and the tract continues and also innervates the MB calyces. lACT PNs innervate T1 glomeruli and their somata lie in the anteroventral and lateral part of the AL (Schäfer, S. *et al.*, 1988). Thus, uniglomerular PNs separate in tracts according to their innervated glomerulus, and the separation corresponds to separate antennal tracts (T1–T4). The molecular mechanisms for this separation are unknown, but some insight comes from flies (see below). Uniglomerular PNs in honeybees have small branches at their exit points of the AL, which may form connections between cells outside their innervated glomeruli, but whose computational function is not yet understood (Müller, D. *et al.*, 2002; Galizia, C. G. and Kimmerle, B., 2004). The initial portion of the lACT is also shared by

multiglomerular fibers that innervate only the LP and the ring neuropil of the α-lobe (Abel, R. *et al.*, 2001). Most multiglomerular PNs, however, use the mlACT, which in fact consists of several small tracts. Their axons also innervate the LP and the neuropil around the α-lobe. Within the AL, they branch sparsely within glomeruli (Fonta, C. *et al.*, 1993; Abel, R. *et al.*, 2001). The number of glomeruli that each multiPN innervates within the AL varies, ranging from a few to many or possibly all.

In *Manduca*, tracts are iACT, mACT, and oACT (Homberg, U. *et al.*, 1988). Most neurons in the iACT are uniglomerular, while most neurons in mACT and oACT are multiglomerular. Axons in the iACT and oACT innervate MB calyces and the LP, while axons in the mACT innervate a variety of foci in the LP but not the MBs (Homberg, U. *et al.*, 1988).

Fly tracts are also named iACT, mACT, and oACT (and, as in other species, these may be subdivided further), but these do not correspond to the moth nomenclature. The inner tract (traveling along the brain midline) has the strongest input to the MB calyces. The medial tract has some axons that innervate the MB calyces, while most axons target only the LP. Axons in the oACT do not innervate the MB calyces. All tracts innervate the LP (Stocker, R. F. *et al.*, 1990; Stocker, R. F., 1994; Strausfeld, N. J. *et al.*, 2003). Thus, *Drosophila*'s iACT and mACT may correspond to the honeybee's mACT and lACT, or the moth's iACT and oACT, respectively. As in bees, glomerular identity and tract are probably related in flies: the GH146 line labels PNs with somata in the anterodorsal cluster (adPN) and lateral cluster (lPN), which have axons that use the iACT and send their dendrites to about 30–35 stereotypical glomeruli (Jefferis, G. *et al.*, 2001; Marin, E. C. *et al.*, 2002; Wong, A. M. *et al.*, 2002; Jefferis, G. S. *et al.*, 2007; Lin, H. H. *et al.*, 2007). The tract used by PNs innervating the remaining glomeruli is unknown. GH146 also labels at least four PNs that use the mACT and at least one PN that uses the oACT. The POU domain transcription factors, Acj6 and Drifter, are expressed in adPNs and lPNs, respectively, and are required for their dendritic targeting (Komiyama, T. *et al.*, 2003). Interestingly, these genes are also necessary for OSN targeting (see Section 4.41.2.3.4).

PN tracts in cockroaches follow an only partially similar nomenclature: the iACT travels along the brain midline, the oACT travels along the optic lobes, and intermediate tracts have been named ACT tracts II, III, and IV (Malun, D. *et al.*, 1993). PNs in iACT are uniglomerular and innervate both the MB calyces and the LP. Pheromone-sensitive PNs in male cockroaches only use the iACT (Malun, D. *et al.*, 1993). PNs in tract II are also uniglomerular and innervate both MB and LP. PNs in the other tracts are multiglomerular and innervate the LP only (tracts III and oACT) or several brain areas including the MBs (tract IV, which originates from the same root in the AL as the oACT) (Malun, D. *et al.*, 1993).

PNs in locusts have a different morphology from what has been described so far. No uniglomerular PNs have been reported yet; rather, within the AL, PNs branch in a limited number of glomeruli (Laurent, G. *et al.*, 1996; Anton, S. *et al.*, 2002). This is reminiscent of the multiple glomeruli innervated by individual OSNs, but the two do not form corresponding groups, that is, PNs innervate groups of glomeruli that do not correspond to groups innervated by an OSN (Anton, S. *et al.*, 2002). In other words, glomerular groups in locusts cannot be functionally analogous to single glomeruli in other insects. In locusts, only a single ACT close to the brain midline connects the ALs to the MB (Leitch, B. and Laurent, G., 1996), but minor tracts that connect the AL to other areas do exist (Ignell, R. *et al.*, 2001).

4.41.2.5.2 Projection neuron numbers

In honeybees, the lACT and mACT probably house about 400 fibers each, and the mlACT much less, giving a total of less than 1000 (Rybak, J., 1994). This figure may represent an upper limit, considering that the number of PNs has also been estimated at 500 (Bicker, G. *et al.*, 1993) or 800 PNs (Hammer, M., 1997).

Manduca has ~400 uniglomerular PNs in the iACT and ~340 in the oACT, and ~122 multiglomerular PNs in the mACT (Homberg, U. *et al.*, 1988).

In *Drosophila*, the GAL4 line that is most often used for investigating properties of PNs is GH146 (Heimbeck, G. *et al.*, 2001). This line labels about 80–90 PNs, of which 85 are uniglomerular and travel in the iACT, with somata in the anterodorsal (40–50) and lateral cluster (30–35), and 6–7 are multiglomerular, do not use iACT, do not innervate the MB, and have their somata in the ventral cluster (Jefferis, G. *et al.*, 2001; Wong, A. M. *et al.*, 2002). The total number of PNs in *Drosophila* is estimated to be 150–200 (Stocker, R. F. *et al.*, 1997). The proportion of multiglomerular PNs with respect to uniglomerular PNs is below 10% in *Drosophila*.

An estimate of cockroach PN number is 250 (Ernst, K. D. *et al.*, 1977). The number of PNs in

locusts is ~830 (Leitch, B. and Laurent, G., 1996), based on counting axon profiles in the main ACT tract.

4.41.2.5.3 Projection neuron transmitters

Most uniglomerular PNs have ACh as transmitter. In bees, mACT PNs are AchE-positive, showing that they use ACh (Kreissl, S. and Bicker, G., 1989). Furthermore, Kenyon cells (KCs) express nicotinic ACh receptors and are activated by ACh (Bicker, G. and Kreissl, S., 1994). Fibers in the honeybee lACT are not cholinergic; they are taurin-immunoreactive (Bicker, G. *et al.*, 1993). No responses to taurin application could yet be measured in cultured KCs (Grünewald, B., personal communication). In moths, ~67 somata associated with the AL stain for AChE, and the oACT leading to the LP and the MB is stained (Homberg, U. *et al.*, 1995). The situation in *Drosophila* is similar, with at least one tract strongly stained for AChE (Yasuyama, K. and Salvaterra, P. M., 1999). In locusts, the ACT tract stains for AChE (Homberg, U., 2002).

Multiglomerular PNs that are GABAergic have been shown in bees (Schäfer, S. and Bicker, G., 1986), moths (Hoskins, S. G. *et al.*, 1986), and flies (Ito, K., personal communication). No other transmitter has so far been associated with multiglomerular PNs.

4.41.2.5.4 Projection neuron physiology

Responses in insect PNs have been measured at the single-cell level with electrophysiological techniques in a variety of species (Hansson, B. S. *et al.*, 1991; Christensen, T. A. *et al.*, 1998a; 1998b; Abel, R. *et al.*, 2001; Müller, D. *et al.*, 2002; Galizia, C. G. and Kimmerle, B., 2004; Wilson, R. I. and Laurent, G., 2005). Optical methods were successful in bees after loading PNs with calcium-sensitive dyes (Sachse, S. and Galizia, C. G., 2002; 2003) and in flies after genetically expressing activity-sensitive proteins (Fiala, A. *et al.*, 2002; Ng, M. *et al.*, 2002; Wang, J. W. *et al.*, 2003; Yu, D. *et al.*, 2004). PNs are spontaneously active in insects, including honeybees (Abel, R. *et al.*, 2001; Galán, R. F. *et al.*, 2005), moths (Christensen, T. A. *et al.*, 1998b), *Drosophila* (Wilson, R. I. *et al.*, 2004), cockroaches (Boeckh, J. *et al.*, 1987), and locusts (Perez-Orive, J. *et al.*, 2002). Against this background, responses to odors can be both excitatory and inhibitory. Their responses are shaped by the AL network (Christensen, T. A. *et al.*, 1998a; Sachse, S. and Galizia, C. G., 2002; Wilson, R. I. and Laurent, G., 2005; Olsen, S. R. *et al.*, 2007; Schlief, M. L. and Wilson, R. I. 2007; Shang, Y. *et al.*, 2007).

Instantaneous response frequencies of excitatory responses can be several hundreds of Hertz and persist over the duration of a 2-s stimulus. In honeybees, lACT neurons tend to respond to many odors with excitation, whereas mACT neurons display more complex responses to different odors, including phases of excitation and inhibition (Abel, R. *et al.*, 2001; Müller, D. *et al.*, 2002). PN physiology is discussed below in more detail (see Section 4.41.3).

4.41.2.6 Feedback Neurons and Biogenic Amines

Neurons that branch in the AL and also in other brain areas have been found in many insect species. There are many different morphologies and biochemical profiles of these neurons, but part of the apparent variability among species might be due to limited knowledge of these cells. Many of these neurons stain with antibodies against biogenic amines (dopamine, serotonin, octopamine, and histamine) and are believed to have a modulatory function, including up- and downregulation, thresholding, motivational states, attention, and learning (Hammer, M. and Menzel, R., 1998; Bicker, G., 1999b; Homberg, U. and Müller, U., 1999). Other possible feedback neurons are the honeybee AL-1 neurons that originate in the MB α-lobe and project widely through the ALs (Rybak, J. and Menzel, R., 1993). Dye injections into single neurons have also revealed the existence of neurons with somata in the subesophageal ganglia (SEG), of which some innervate only a few glomeruli in the AL symmetrically on both sides, and send collaterals to the MB (Abel, R. *et al.*, 2001).

I review evidence for biogenic amines (Bicker, G., 1999b; Monastirioti, M., 1999; Homberg, U., 2002) in the order dopamine, octopamine (Stevenson, P. A. and Sporhase-Eichmann, U., 1995; Roeder, T., 1999; Pflüger, H. J. and Stevenson, P. A., 2005), serotonin (Homberg, U., 2002), and histamine (Nässel, D. R., 1999).

Dopamine: Dopamine has been found in many insect ALs, but there is considerable variation in its presence and distribution (Homberg, U. and Müller, U., 1999). In honeybees, four large dopamine-immunoreactive cells innervate the glomeruli and central neuropil of each AL. Two of their somata lie in the dorsolateral cell-body rind of the AL and the other two close to the dorsal rind of the SEG (Schäfer, S. and Rehder, V., 1989). These neurons form a fine plexus both in the central neuropil of the AL and in the glomeruli and also branch in the DL, the

protocerebrum, and the SEG. Within the glomeruli, they are restricted to the core (Schürmann, F. W. *et al.*, 1989). While there are dopaminergic neurons in moth brains, their precise morphology is not yet known (Mesce, K. A. *et al.*, 2001). No dopamine was found in fly ALs (Nässel, D. R. and Elekes, K., 1992; Friggi-Grelin, F. *et al.*, 2003). In cockroaches, there are dopaminergic centrifugal neurons, and in addition, some LNs are dopamine-positive (Distler, P. G., 1990). In locust ALs, no dopamine immunoreactivity was found (Wendt, B. and Homberg, U., 1992).

Octopamine: All honeybee glomeruli contain octopamine-immunoreactive fibers, deriving from very few profiles entering the AL from ventroposterior. Within the outer cap of the glomeruli, these fibers appear to be of considerably larger diameter than the very thin fibers in the glomerular centers (Kreissl, S. *et al.*, 1994). A neuron that most likely uses octopamine in honeybees is the ventral unpaired median cell of maxillary neuromere 1 (VUMmx1), which has an unpaired soma in the subesophageal ganglion. Apart from the AL, this neuron has branches in the subesophageal ganglion itself and in the protocerebrum (MB and LP). The input–output relationship in the innervated areas is unknown (Kreissl, S. *et al.*, 1994; Bicker, G., 1999b). Functionally, it represents (part of) the unconditioned stimulus (US) in an appetitive learning paradigm (Hammer, M., 1993). When a honeybee is presented an odor (conditioned stimulus, CS) and rewarded with sugar water (US), she will extend the proboscis to lick the sugar water (proboscis extension reflex (PER)). After the learning trial, odor alone elicits a PER (classical or Pavlovian conditioning). Replacing the US with a depolarization of VUMmx1 also leads to an association, and preventing VUMmx1 to spike by hyperpolarizing it during a sugar water stimulus impairs learning (Hammer, M., 1993). In honeybees, octopamine is also related to division of labor within the hive (Schulz, D. J. *et al.*, 2002).

Octopamine is also present in fine arborizations within the AL in moths (Homberg, U. and Müller, U., 1999). These arborizations probably derive from at least three VUM neurons that also innervate the MBs, somewhat reminiscent of VUMmx1 in honeybees (Dacks, A. M. *et al.*, 2005). However, the detailed anatomy of these neurons is quite different between bees and moths, leaving their homology in doubt (Dacks, A. M. *et al.*, 2005). In the moth's periphery, octopamine increases responses to pheromones, but not to general odors (Pophof, B., 2002). In flies, a cluster of neurons in the SEG (SM cells) has a similar morphology to the honeybee VUM neurons, also innervating the ALs (Monastirioti, M., 1999). Octopaminergic neurons in the cockroach AL branch similar as in honeybee (Sinakevitch, I. *et al.*, 2005). In locusts, octopamine is present in fine arborizations within the AL (Homberg, U. and Müller, U., 1999), probably from dorsal unpaired neurons (DUM) in the SEG (Bräunig, P., 1991; Stevenson, P. A. and Sporhase-Eichmann, U., 1995).

Serotonin: In honeybees, there are two paired neurons immunoreactive for serotonin (5-hydroxytryptamine (5HT)), one in each side of the body, called the deutocerebral giant (DCG) neurons, which innervate the ipsilateral AL, the DL, and the SEG and descend into the ventral nerve cord. Their somata lie in the dorsolateral cell body cluster of the AL (Rehder, V. *et al.*, 1987). Within the glomeruli, serotonergic fibers are restricted to the outer cap (Schürmann, F. W. and Klemm, N., 1984). Two serotonergic neurons in the moth *M. sexta* have been well characterized (Kent, K. S. *et al.*, 1987; Sun, X.-J. *et al.*, 1993b). These neurons have their soma close to the AL and branch in the core of all glomeruli within the contralateral AL, without forming overlap with OSN afferent fibers that innervate the outer cap. They receive input in the superior protocerebrum, the MB, and the lateral accessory lobes. This anatomy suggests a role as feedback neurons, or as centrifugal modulators of AL responses. In flies, there are two serotonergic neurons associated with each AL that branch in olfactory glomeruli (Nässel, D. R., 1988). A pair of serotonergic neurons is also found in cockroaches, where each neuron has a soma in the AL, extending a neurite to the protocerebrum including the MB and then back to the AL where it branches and makes output synapses in most if not all glomeruli (Salecker, I. and Distler, P., 1990). In locusts, there are three serotonin-positive cells in each AL, innervating all glomeruli. These neurons are multiglomerular PNs that project toward the MB, without entering them. One has an axon in the iACT, and the other in an intermediate ACT (dmACT) (Ignell, R. *et al.*, 2001).

Histamine: In the honeybee AL, there are ~35 LNs that are immunoreactive for histamine (Bornhauser, B. C. and Meyer, E. P., 1997). Histamine acts as an inhibitory transmitter in this species (Sachse, S. and Galizia, C. G., 2002). In moths, histamine is not present in LNs, but it is present in two centrifugal neurons that innervate both ALs each and that also arborize in the AMMC and the SEG (Homberg, U. and Hildebrand, J. G., 1991). There

are no histaminergic neurites in *Drosophila* ALs (Nässel, D. R., 1999). Histamine is found in cockroach LNs, with a few somata around the ALs, and possibly a tract connecting to the AL ventrally (Pirvola, U. *et al.*, 1988). In the locust, there is one histamine-positive neuron in each AL that projects to the LP (Ignell, R. *et al.*, 2001).

4.41.2.7 Glial Cells

Glial cells have been analyzed in several insect species, including bees (Hähnlein, I. and Bicker, G., 1996), *Drosophila* (Jhaveri, D. *et al.*, 2000; Jhaveri, D. and Rodrigues, V., 2002; Jhaveri, D. *et al.*, 2004), cockroaches (Prillinger, L., 1981), and locust ALs (Hähnlein, I. *et al.*, 1996). Glial cells are certainly best known in moths (Kretzschmar, D. and Pflugfelder, G. O., 2002; Oland, L. A. and Tolbert, L. P., 2003; Tolbert, L. P. *et al.*, 2004). The cells are prominent on the outside of the AL and form thin processes that digitate between glomeruli well into the AL, thus separating them from each other. Glial cells are invisible in light microscopy and difficult to discern in electron microscopy. In species where glomeruli are arranged around a central, nonglomerular neuropil (coarse neuropil, e.g., honeybees, moths) glial cells do not form a border between glomeruli and the central neuropil. It should be noted that there is no universal glial cell marker in insects and that glial fibrillary acidic protein (GFAP) does not label insect glial cells.

Several different types of glial cells are associated with the AL. Along the antennal nerve, glial cells with long processes and multiple expansions enwrap axon fascicles. OSN axons travel as parallel bundles within the antennal nerve, but as they approach the AL, they reach a so-called sorting zone, where they form a dense and complex network, which results in a rearrangement of neighborhood relationships that ultimately leads to appropriate glomerular targeting. Glial cells are necessary for this rearrangement to occur (Oland, L. A. *et al.*, 1988; Rössler, W. *et al.*, 1999b). Within the AL, there are at least two glial-cell types that form borders around glomeruli: one has large cell bodies and branching, vellate arbors and the other has multiple, mostly unbranched processes with many lamellate expansions along their length that surround glomeruli as part of a multilamellar envelope (Oland, L. A. *et al.*, 1999). Glia in the neuropil is instrumental for protoglomerulus formation and proper development of the AL (Baumann, P. M. *et al.*, 1996). These mechanisms are mediated by direct contact between the OSN axon growth cones and the glial cells themselves, as shown *in vitro* (Tucker, E. S. and Tolbert, L. P., 2003; Tucker, E. S. *et al.*, 2004).

In the adult, glial cells might help keeping neural activity separate between glomeruli, and thus increasing the discriminatory power of the system. Goriely and colleagues simulated the movement of K^+ ions within the AL in a mathematical diffusion model based on electron microscopic data and found that the glial envelope could efficiently reduce ion movement between glomeruli. Since K^+ accumulation in extracellular space causes cell depolarization, this barrier might prevent cross talk between adjacent glomeruli (Goriely, A. R. *et al.*, 2002). Glia might also form a sink for the gaseous messenger NO, given that NO is involved in glial cell physiology (Gibson, N. J. *et al.*, 2001).

4.41.2.8 Cellular Organization and Number Relationships

What is the numerical relationship of the different neuron types in the AL, and how many neurons of each type innervate each glomerulus? The numbers differ widely among insects. For example, a single honeybee glomerulus is innervated on average by almost 400 OSNs (60 000 OSNs onto 160 glomeruli), 1000 LNs (as a gross estimate, assuming a total of 4000 LNs, with each innervating an average of 40 glomeruli), and 5 PNs (800 PNs in 160 glomeruli). The fruit fly *D. melanogaster* has fewer OSNs, but since most OSNs project into the ALs of both sides, the relationship of OSNs and glomerulus is 50:1. Each glomerulus is innervated by three PNs, on average (Wong, A. M. *et al.*, 2002). These average considerations do not consider that OSNs of different classes vary greatly in number, and therefore, the convergence/divergence ratio might span a wide range in different glomeruli not only across species but also within a species.

4.41.3 Functional Organization in the Antennal Lobe

Is it possible to attribute functional tasks to each neuron type in the AL? In a greatly simplified picture, the answer is yes, as developed elsewhere (Sachse, S. and Galizia, C. G., 2005). An interpretation of the main cell types forming the AL circuitry could then be as follows (see below for more details).

1. Homogeneous LNs uniformly innervate the AL and accomplish a gain control function. They set the background activity close to the threshold, thus optimizing the system's sensitivity. They also protect the system from overloading and are ideal candidates for driving oscillations.
2. Heterogeneous or asymmetric LNs enhance the contrast of across-glomeruli patterns by unidirectional connections between input glomeruli and output glomeruli.
3. Excitatory LNs may distribute information accross glomarular boundaries or amplify responses within glomeruli (see above).
4. Multiglomerular PNs have access to the entire AL. They may respond to global activity and thus give information about stimulus timing (onset/offset) and concentration and would be ideal candidates for cellular learning in the AL.
5. Uniglomerular PNs extract the activity of single glomeruli and project to higher-order brain centers. The identity of an odor is encoded in the combinatorial activity pattern across their axons' identities.

4.41.3.1 Odor-Evoked Activity Across Glomeruli

When an animal is challenged with an odor, many different receptor neurons are activated. Their axons send that activity to the AL in the form of AP trains. Due to the convergence of functionally equivalent axons onto individual glomeruli, the result is a pattern of glomeruli that are activated to a varying degree. Therefore, activity patterns across glomeruli are not binary (on/off), but continuous (each glomerulus can be activated to varying degrees). The resulting combinatorial odor patterns are sufficient, in terms of the information contained in the patterns, to identify an odor, and therefore could represent the olfactory code. However, it is not known what information is really used by the brain, and therefore, the biological olfactory code remains to be deciphered.

Odor-evoked combinatorial patterns can be measured with imaging techniques, because this allows for measuring several combinatorial odor responses across glomeruli within individual animals. Unfortunately, the temporal resolution is not yet sufficient to resolve individual APs, and therefore, imaging studies are limited to measuring time-averages of neural activity.

Responses have been measured in *D. melanogaster* by using genetically encoded reporter proteins. synaptopHluorin was used to measure synaptic vesicle release (Ng, M. *et al.*, 2002; Yu, D. *et al.*, 2004) and cameleon or G-CaMP for intracellular calcium (Fiala, A. *et al.*, 2002; Wang, J. W. *et al.*, 2003; Suh, G. S. *et al.*, 2004). These proteins were expressed under the control of specific promoters, which allow for a good reproducibility of the measured cells. For example, using the GAL4 line GH146, a reporter protein can be expressed in a population of brain cells that within the AL only consists of PNs. Similarly, expressing the reporter in GABAergic cells allows to exclusively measure inhibitory cells (mostly LNs, and a subpopulation of PNs). However, the relative contribution of different cell groups labeled by the same genetic line cannot be separated if they overlap spatially. Currently, the clearest separation can be expected from OSN populations, where reporter proteins can be driven to be expressed in all cells that also express ORs, or just a particular OR.

In species that do not have the molecular power of *Drosophila*, synthetic reporters can be used to stain the cells. Bath application of calcium-sensitive dyes has revealed odor responses in bees (Joerges, J. *et al.*, 1997; Galizia, C. G. and Menzel, R., 2001), ants (Galizia, C. G. *et al.*, 1999a), and moths (Galizia, C. G. *et al.*, 2000a; Carlsson, M. A. *et al.*, 2002; Hansson, B. S. *et al.*, 2003). Because the dye is applied in the bath, the exact proportion of measured cells cannot be determined and might include all neuron types as well as glial cells, making a cellular interpretation of the results difficult. In bees, however, the response magnitude (though not the time course) is a good estimate of receptor neuron response for each glomerulus (Galizia, C. G. and Vetter, R. S., 2004). In moths, measurements of released NO closely mirror the activity patterns measured with bath-applied calcium dyes (Collmann, C. *et al.*, 2004). Since in moths NO is produced only by OSNs (Gibson, N. J. and Nighorn, A., 2000), this suggests that also in this species the (bath-applied) calcium indicator response magnitude can be used to estimate OSN activity for each glomerulus. Time courses of these calcium responses do not correspond to electrophysiological measurements of OSNs: they rise continuously during the stimulus and decay slowly following the shape of a mathematical α-function (Stetter, M. *et al.*, 2001). Odor responses can also be measured with voltage-sensitive dyes (VSDs) (Galizia, C. G. *et al.*, 1997; 2000b). PNs can be measured without a contribution from other cell types if they are backfilled from the protocerebrum (Sachse, S. and Galizia, C. G., 2002; 2003). These selective stainings lead to calcium

responses that are fast, with a steep rise at stimulus onset and a steep decay at stimulus offset. As in mammals (Xu, F. *et al*., 2000; Leon, M. and Johnson, B. A., 2003), the spatial odor-response patterns have also been recorded using 2-DG labeling in fruit flies (Buchner, E. and Rodrigues, V., 1983; Rodrigues, V. and Buchner, E., 1984) and in *Calliphora* (Distler, P. G. *et al*., 1998a). This brings the advantage of having a permanent preparation, but the disadvantage of having but one measurement per animal, and no dynamic information.

An important strength of insect preparations is that glomeruli can be identified among animals, given their small number and their characteristic arrangements. Using VSD in honeybees allows recognizing the glomerular layout very clearly in the staining pattern (Galizia, C. G. and Vetter, R. S., 2004). This shows that activity patterns are indeed glomerular, that is, that the boundaries of highly active regions coincide with the boundaries of individual glomeruli. With identifiable glomeruli, comparison and characterization is straightforward. Even in species where a morphological atlas of glomeruli is not yet available, or when identifying glomeruli is not possible, odor-evoked patterns are so stereotype among individuals that a direct quantification can often be achieved (Meijerink, J. *et al*., 2003; Skiri, H. T. *et al*., 2004).

A recent development in insect olfactory recordings is the use of multielectrode arrays, which allow the simultaneous extracellular recording of many neurons but do not allow identifying the neurons involved (Christensen, T. A. *et al*., 2000).

4.41.3.2 Processing in the Antennal Lobe

The only olfactory information that is available to the brain must be present in OSN activity. However, not all information present in the OSNs is kept in PNs. The cellular network formed by OSNs, LNs, and PNs extracts information and creates a modified odor representation. The activity patterns across PNs are combinatorial and temporally fluctuating.

4.41.3.2.1 Contrast enhancement in the antennal lobe

In the AL network, an input layer (OSN) is transformed by internal connections (LNs) into an output layer (PNs). This resembles a neural network as it is often used in computational neurobiology (Getz, W. M., 1991; Linster, C. *et al*., 1994; Getz, W. M. and Lutz, A., 1999; Brody, C. D. and Hopfield, J. J., 2003), and indeed, the AL has often been modeled as such (Getz, W. M., 1991; Linster, C. *et al*., 1994; Getz W. M. and Lutz, A., 1999; Rabinovich, M. I. *et al*., 2000; Bazhenov, M. *et al*., 2001). Since both input and output are organized in the same glomeruli, this network has the additional beauty of having equal dimensionality for input and output. Therefore, the question of what role the hidden layer plays can easily be addressed by comparing the glomerular activity of PNs with the glomerular activity in the OSNs. This approach has been taken in several studies, with surprisingly disparate results. In optical imaging studies in *Drosophila*, the difference between PNs and OSNs was so small that no apparent processing was deducible (Ng, M. *et al*., 2002; Wang, J. W. *et al*., 2003). In an electrophysiological study comparing the input and the output of glomerulus DM2, also in *Drosophila*, the response spectrum was apparently broader in PNs than in OSNs (Wilson, R. I. *et al*., 2004). Comparing the input and the output for odor-concentration dose–response curves in honeybees showed that glomeruli with a low threshold for an odor have almost identical dose–response curves in PNs and in OSNs, while less-sensitive glomeruli have a shifted dose–response curve in PNs, showing that at higher concentrations LNs suppress these PN responses (Sachse, S. and Galizia, C. G., 2003). Thus, within 2 years, publications suggesting no change, response broadening, and response sharpening have been published. One difficulty arises from comparing activity across different neuron populations (OSNs and PNs). Conceptionally, the quantitative interpretation of such a comparison is impossible, because the conversion rate of neural activity is unknown. In electrophysiological studies, an AP in an OSN has a different value from an AP in a PN, and therefore, comparing AP numbers *per se* is impossible. For example, one AP in an OSN might be sufficient to strongly depolarize the PNs in the innervated glomerulus (given the high convergence of many OSNs in that glomerulus and the many synapses made by each OSN axon), while even several APs in a PN might not represent a significant signal in the MBs (given the high spontaneous activity level in these neurons and the possible need for APs to synchronize with other APs). The same argument is valid when optical signals are measured: calcium measurements record changes due to several intracellular cascades of dendritic and presynaptic calcium, and the measurements of synaptic exocytosis are similarly affected. Furthermore, transfer functions among neurons are not linear, again clouding a quantitative comparison of different neuron populations.

Therefore, the question of what the population of LNs is computing within the AL has to be addressed with different techniques. Linster C. and coworkers (2005) created a computer model of the AL and ran experimental data from honeybees under different assumptions about the connectivity of the LN network, comparing three network types: one where LNs interconnect neighboring glomeruli, one with stochastic connections, and one based on the odor-response properties of glomeruli. This approach avoids comparing PN and OSN activity directly but rather compares different network architectures and finds the one that matches best with experimental data. The results show that, in honeybees, inhibitory connections are strongest among glomeruli that have similar odor-response profiles, and weakest among glomeruli that do not overlap in their odor-response profiles, irrespective of their spatial position (Linster, C. *et al.*, 2005). This leads to an optimization of odor responses in PNs across odors, by reducing response overlap to similar odors, and supports the theory that the AL sharpens odor-response profiles.

Such a glomerulus-specific network is likely to be realized by heteroLNs, which densely innervate one glomerulus and diffusely innervate a limited number of other glomeruli. Because these neurons are not symmetrical, a glomerulus A that inhibits a glomerulus B does not need to receive inhibitory input from B. Physiological evidence for such a nonsymmetrical connectivity has been found in bees (Sachse, S. and Galizia, C. G., 2002). Interestingly, in behavioral experiments where odor similarity was studied, such an asymmetry has also been found: similarity from an odor A to B does not imply the same similarity from odor B to A (Guerrieri, F. *et al.*, 2005).

4.41.3.2.2 Sensitivity optimization in the antennal lobe

Some OSNs are active even without a stimulus, but this activity is not temporally complex. On the other hand, many electrophysiological recordings show that PNs are spontaneously active with a pronounced temporal complexity. As a consequence, continuously changing glomerular activity patterns are seen across glomeruli (for example see Relevant Websites section) (Sachse, S. and Galizia, C. G., 2002; Galán, R. F. *et al.*, 2005). If the response strength were normalized, an experimenter would not be able to distinguish individual events of spontaneous activity from odor-evoked responses. The spontaneous activity might result from a mechanism that increases the sensitivity to weak odors (Sachse, S. and Galizia, C. G., 2005). In this model, PNs can be compared to a loaded spring. An inhibitory feedback loop of LNs keeps PNs at firing threshold, so that minimal olfactory stimuli will suffice to elicit an odor-evoked pattern. In order to maintain PNs at threshold, their depolarization must constantly be probed, which is apparent as spontaneous activity. Such a mechanism may seem to interfere with a reliable representation of odor concentration. However, measuring odor concentration is much more affected by odor adaptation at the periphery, a phenomenon known from all sensory systems. Due to the phasic response properties of OSNs, the olfactory system always measures concentration changes rather than absolute concentrations. In the adapted state, the loaded spring model of the AL therefore ensures that even small increases in odor concentration will lead to them being detected by the animal. The strength of the olfactory stimulus (i.e., the concentration change magnitude) remains reliably coded in the response magnitude change across olfactory glomeruli (Sachse, S. and Galizia, C. G., 2005).

4.41.3.2.3 Temporal activity structures

Odor responses are already temporally structured at the level of OSNs: some OSNs have phasic, some have tonic responses, some have activity that outlasts the odor stimulus, and some reduce activity upon olfactory stimulation (de Bruyne, M. *et al.*, 2001). As a consequence, an olfactory stimulus that is temporally uniform leads to a pattern of activity that is temporally complex. In addition, in the natural environment of insects, odors themselves are temporally complex due to air turbulence (Murlis, J. *et al.*, 1992; Justus, K. A. *et al.*, 2005). This complicates the analysis of temporal patterns within the brain, suggesting that slow patterns might predominantly reflect stimulus variation (Vickers, N. J. *et al.*, 2001).

Response properties on a fast temporal scale can only be measured with electrophysiological techniques. Single-cell recordings allow to fill neurons with a dye and then to identify the glomerulus that was innervated (Müller, D. *et al.*, 2002; Galizia, C. G. and Kimmerle, B., 2004). Slow temporal structures consisting of sequences of bursts and inhibitory events are found in PNs in all insects studied so far, including moths (Christensen, T. A. *et al.*, 1998b), locusts (Laurent, G., 1996), and honeybees (Abel, R. *et al.*, 2001; Müller, U. and Hildebrandt, H., 2002). In locusts and honeybees, blocking chloride channels with Picrotoxin does not prevent these slow temporal patterns (MacLeod, K. and Laurent, G., 1996;

Stopfer, M. *et al*., 1997) but modifies them (Sachse, S. and Galizia, C. G., 2002). This suggests that they may partially originate in the OSN input or from a Picrotoxin-insensitive inhibitory network.

Behavioral studies have shown that olfactory decisions are taken rapidly in rats (Uchida, N. and Mainen, Z. F., 2003; Abraham, N. M. *et al*., 2004) and in bees (Ditzen, M. *et al*., 2003). This time was ~200 ms for mice and ~690 ms for honeybees, which included the time needed for olfactory recognition as well as motor responses and physical displacement of the animal. The time needed for olfactory discrimination is not affected by the difficulty of the olfactory task in terms of odor similarity or concentration (Ditzen, M. *et al*., 2003; Uchida, N. and Mainen, Z. F., 2003), or the difference in time, when present, is small (Abraham, N. M. *et al*., 2004). Physiological studies of PN responses show that 200–300 ms in locusts (Stopfer, M. *et al*., 2003) and 400 ms in bees (Galán, R. F. *et al*., 2004) are needed to reach the most distinct odor classification in the AL irrespective of odor concentration. Therefore, the later phases of slow activity components cannot be behaviorally relevant for odor discrimination. However, these late activities might play a role in olfactory learning or other aspects of olfactory processing that might occur after discrimination has taken place. An argument in favor of this interpretation is that odor representation is ameliorated during the first 2 s after stimulus onset, leading to a clearer distinction of odors (Galizia, C. G. *et al*., 2000b; Friedrich, R. W. and Laurent, G., 2001).

Fast temporal structures are evident in odor-evoked oscillations, which are found almost ubiquitously in olfactory systems. So far, within insects, only *Drosophila* seems not to respond with oscillation (Wilson, R. I. *et al*., 2004), while cockroaches (27 Hz), locusts (22 Hz), bees (30 Hz), wasps (17 Hz) all do (Stopfer, M. *et al*., 1999), and moths also (Heinbockel, T. *et al*., 1998). Applying Picrotoxin abolishes these oscillations (MacLeod, K. and Laurent, G., 1996; Stopfer, M. *et al*., 1997) and also modifies the spatial activity patterns across glomeruli (Sachse, S. and Galizia, C. G., 2002). Oscillations originate from many PNs firing APs simultaneously, due to a rhythmical inhibition from LNs that branch over large areas within the AL and the brain. Because individual PNs do not fire in every oscillation cycle, and because some APs also occur out of the rhythmic synchrony pattern, a model of olfactory coding has been proposed where odor identity would be encoded in sequences of changing PN ensembles (Laurent, G., 1999). However, other interpretations for synchronized APs have also been proposed, where synchrony would be more related to odor concentration or intermittency rather than to odor quality (Christensen, T. A. *et al*., 2000).

4.41.3.3 Combinatorial Odor Codes

Odors evoke combinatorial patterns of activated glomeruli, with each glomerulus participating in activity to many odors. These patterns are conserved among individuals (Galizia, C. G. *et al*., 1999c; Wang, J. W. *et al*., 2003), which is a consequence of the innate mapping of OSNs that express a given OR to individual glomeruli (Vosshall, L. B. *et al*., 2000; Couto, A. *et al*., 2005; Fishilevich, E. and Vosshall, L. B., 2005). As a corollary, patterns are also bilaterally symmetrical (Galizia, C. G. *et al*., 1998).

MRRs are best described as (some more, some less) broadly tuned to a best molecule (Sachse, S. *et al*., 1999). Importantly, there are no glomeruli for functional groups or other chemical parameters (e.g., aldehyde or C6 carbon chain). While some glomeruli preferentially respond to one functional group rather than another when tested for aldehydes, ketones, alcohols, carbon acids, or alkanes, they always respond also to other functional groups, even though the response is weaker. Furthermore, they always have a particular preferred range of molecule size to which they respond. Therefore, the response profile of individual glomeruli is not determined by particular features of the odorant (sometimes referred to as odotopes), such as ketone group or aldehyde, and the olfactory code is not a building set, where 1-heptanol would be coded in an alcohol glomerulus plus a C7 aliphatic chain glomerulus.

4.41.3.4 Coding Odor Concentration and Odor Mixtures

With increasing concentration, activity increases both in magnitude and in number of active glomeruli. As a corollary, with decreasing concentration, activity decreases and consists of a single glomerulus being active at very low concentration. This is a direct consequence of the receptors' MRRs that form the input: each receptor has a few substances to which it responds with a higher affinity than any other receptor, and at its lowest effective concentration, that substance will elicit a combinatorial pattern of activity in the AL that consists of that single glomerulus being active, and all other glomeruli being silent. At higher concentrations, many glomeruli are active, and every glomerulus takes

part in activity patterns of several odors. Again, this is a direct consequence of the broadening MRR of receptors with increasing concentrations. PN responses in honeybees are qualitatively stable over a concentrations range of up to 4 log units, because higher odor concentrations increase total response intensity without changing the relative intensity across glomeruli; at the input level, however, the activity patterns are more affected by concentration differences (Sachse, S. and Galizia, C. G., 2003). Thus, the neural network within the AL contributes to concentration invariance.

Mixture coding is complex and far from understood in insects. Most naturally occurring odors consist of a large number of volatile compounds. Additionally, the turbulent nature of air leads to odor plumes being mixed in a chaotic fashion (Murlis, J. *et al.*, 1992). This creates a difficult task for the olfactory system: should it create a synthetic representation of the blend, or rather an analytical separation of the components, or both? Several studies have asked how many odors animals can differentiate in a mixture. However, results cannot be generalized: perfumers know that some odors do blend, while others do not. Therefore, the number of discriminable odors depends on the quality of the odors mixed. Electrophysiological studies have also shown different kinds of mixture interactions. The presence of an odor B can interfere with the normally strong response to an odor A, which is termed mixture suppression. Conversely, a neuron or glomerulus may respond to a binary mixture with a response that exceeds the summed responses to the single components, defined as synergism. An inhibitory network within the AL optimized for sharpening odor-response patterns should have the effect of creating stronger mixture interactions with similar odors than with odors that elicit nonoverlapping response patterns. Psychophysically, this implies that similar odors in a mixture compose a new odor, which should make it difficult for the olfactory system to extract the identity of the odor components (synthetic representation), while mixtures of dissimilar substances are represented as the sum of the optimized representation of each component (analytical representation) (Wilson, D. A. and Stevenson, R. J., 2003). Behavioral data in rats support this idea by showing that rats perceive binary mixtures composed of dissimilar odors as very similar to their components, whereas binary mixtures containing similar odors appeared dissimilar to the animal (Wiltrout, C. *et al.*, 2003). By increasing the number of components in an odor mixture, mixture interactions are likely to increase and further reduce the similarity to the single-component patterns (Deisig, N. *et al.*, 2003). With this coding strategy of odor mixtures, the olfactory system implements a logic that allows a unique representation of odor mixtures without saturating the olfactory code, at the expense of a loss in analytical capacity.

4.41.3.5 Coding of Special Odors

There are several chemosensory tasks that are special for olfactory systems. Among them are pheromones (which can be further subdivided into sexual and nonsexual pheromones), CO_2 concentration, humidity, and contact (nontaste) odors.

4.41.3.5.1 Sexual pheromones

The sexual pheromone system is the classic example for a labeled line system, with each OSN type, and consequently the corresponding glomerulus, representing a component of the pheromone blend. Glomeruli specific for sexual pheromones do not have a broad response spectrum in the natural environment of the species, because none of the other ligands that exist (and are known) occur in nature. For example, in *M. sexta*, the sexual pheromone is a blend of two chemicals, the main component (*E*,*Z*)-10,12-hexadecadienal and the secondary component (*E*,*E*,*Z*)-10,12,14-hexadecatrienal. A different and more stable molecule, (*E*,*Z*)-11,13-pentadecadienal, is a good mimic and is routinely used instead in physiological experiments (Christensen, T. A. and Hildebrand, J. G., 1997). However, because it does not occur in nature, this glomerular activity channel is uniquely activated by its natural ligand within a natural environment (Kaissling, K. E. *et al.*, 1989). Female moths do not have a macroglomerular complex, since they are not receptive to sexual pheromones. They do, however, have a group of large, female-specific glomeruli that respond to plant-derived odors and might also be involved in odor-driven navigation (Reisenman, C. E. *et al.*, 2004).

Sexual pheromones in *Drosophila* are not involved in long-distance navigation, but rather part of a close-encounter olfactory display, that is detected by contact chemoreceptors. The only candidate for a volatile pheromone is *cis*-vaccenyl acetate (Costa, R., 1989; Amrein, H., 2004). Its precise behavioral significance remains to be elucidated, and includes attractive, repellent, and sex specific effects. There are several OSNs sensitive to *cis*-vaccenyl acetate. Cells expressing dOr67d reside in T1 sensilla on

the antenna and mediate sex recognition (Xu, P. *et al.*, 2005; Kurtovic, A., *et al.*, 2007), while cells expressing dOr65a reside in T3 sensilla and mediate generalization of courtship learning (Ejima, A., *et al.*, 2007).

The sexual pheromone of bees consists of several substances, with 9-keto-2(*E*)-decenoic acid (9-ODA) as main component, often referred to as queen's substance. Drones find queens using both olfactory and visual cues, that is, they follow her scent trail, and they identify a dark spot against the bright sky. Mating occurs while flying. The male AL is entirely different from the female, with a limited number of ordinary glomeruli, and four large macroglomeruli (Arnold, G. *et al.*, 1985). Macroglomeruli have complex substructures. In optical imaging experiments, small areas within macroglomeruli respond to many odors, suggesting a more complex arrangement than just separation of sexual pheromone processing from other odors (Sandoz, J. C. and Galizia, C. G., unpublished data). Queen's substance is also a social pheromone within the hive and prevents the emergence of new queens when it is present (Moritz, R. F. A. and Southwick, E. E., 1992).

4.41.3.5.2 Nonsexual pheromones

Nonsexual pheromones differ chemically from sexual pheromones in that they are often less complex molecules that may also be encountered as environmental odors. They sometimes also act as kairomones, as for the case of alarm pheromones that can elicit alarm in sympatric species (Hölldobler, B. and Wilson, E. O., 1990). Ants have a well-developed intraspecific communication system based on pheromones, which they use to communicate food sources, trails, alarm, and more (Hölldobler, B. and Wilson, E. O., 1990). In the ant *Camponotus rufipes*, activity elicited by environmental odors and by pheromonal substances overlap in the AL, suggesting that the two systems share their olfactory circuitry (Galizia, C. G. *et al.*, 1999a).

Important nonsexual pheromones for bees are citral and geraniol, both components of the Nasanov gland, a gland important for the social cohesion of the hive (Free, J. B., 1987): isoamyl acetate, which is the major component of the alarm pheromone associated with the sting apparatus (Free, J. B., 1987; Nuñez, J. *et al.*, 1997), and the repellent scent-marker 2-heptanone, which bees use to mark already visited flowers, thus avoiding revisiting a depleted nectar source (Giurfa, M. and Nunez, J. A., 1992; Giurfa, M., 1993). All of these substances elicit activity in the same region as environmental odors (Joerges, J. *et al.*, 1997; Galizia, C. G. and Menzel, R., 2001). Isoamyl acetate elicits strong responses in several glomeruli, among which T1-48, a glomerulus that is also activated by orange, clove oil, limonene, and several plant extracts. It is unknown whether there is a parallel, more 'labeled line'-like pathway for nonsexual pheromones, reminiscent of the macroglomerular system for sexual pheromones. If there is, this system is certainly not in the T1 region, whose response profiles have already been well mapped but could be located in the T2, T3, or the T4 glomeruli.

Aggregation pheromones are also found, e.g., in male Colorado beetles (Dickens, J. C. *et al.*, 2002). Some aggregation pheromones are effectively sexual pheromones. For example, the ceranbycid beetle *Neoclytus acuminatur* releases a species-specific aggregation pheromone that attracts both sexes (Lacey, E. S. *et al.*, 2004). As with sexual pheromones, aggregation pheromones are quite different for closely related beetles and may be involved in species segregation (Symonds, M. R. and Elgar, M. A., 2004). This is different in fruit flies, where aggregation pheromones are also found but do not form boundaries among species (Symonds, M. R. and Wertheim, B., 2005).

4.41.3.5.3 Carbon dioxide

Carbon dioxide detection is widespread among arthropods, with a wide variability in structure and function (Bogner, F. *et al.*, 1986; Kleineidam, C. and Tautz, J., 1996; Stange, G. and Stowe, S., 1999). CO_2-sensitive sensilla can be hairs, pegs, plugged, or open grooves and can be on the surface or located within a depression or a pit with a restricted opening (Keil, T. A., 1996; Stange, G. and Stowe, S., 1999). Similarly, the functional context for CO_2 detection differs. In hematophagous insects, including Ixodidae and Diptera, CO_2 sensitivity might be related to finding the host (Grant, A. J. *et al.*, 1995; Dekker, T. *et al.*, 2002). Insects that live in confined spaces, such as centipedes or beetle larvae, are capable of sensing CO_2. Similarly, social insects that live in hives (ants, bees, and termites) monitor CO_2 with tonic receptors and control its concentration in a manner reminiscent of homeostatic control (Lacher, V., 1964; Stange, G. and Stowe, S., 1999; Weidenmüller, A. *et al.*, 2002). For moths, in particular nocturnal moths feeding on nectar, CO_2 might be a component of the attractive flower odor, given that flowers that produce high-quality nectar also release considerable amounts of metabolic CO_2 (Guerenstein, P. G. *et al.*, 2004; Raguso, R. A., 2004; Thom, C. *et al.*, 2004).

Drosophila is repelled by CO_2, and a role of this gas as a component of a stress signal has been suggested (Suh, G. S. *et al.*, 2004). However, CO_2 is also produced by rotting fruit, and by fly aggregations on such fruit that might indicate good ovipositioning sites. In the AL, CO_2 activates the V glomerulus. It is innervated by OSNs located on the maxillary palps. These OSNs express two receptors: dGR21a (de Bruyne, M. *et al.*, 2001; Suh, G. S. *et al.*, 2004) and dGr63a (Jones, W. D., *et al.*, 2007) and do not coexpress the otherwise common coreceptor dOR83b (Larsson, M. C. *et al.*, 2004). The innate avoidance behavior to CO_2 is abolished when these OSNs are silenced, suggesting that there is no parallel, additional CO_2 channel (Suh, G. S. *et al.*, 2004). A homologous glomerulus is present in mosquitoes, where it is innervated by OSNs on the mouthparts (Distler, P. G. and Boeckh, J., 1997b). Similarly, CO_2-sensitive OSNs are located in a pit organ on the labial palps in moths, and their axons form glomeruli in the dorsal area of the AL (Kent, K. S. *et al.*, 1986). In locusts and cockroaches, these fibers project close to the AL but do not form a glomerulus within the AL (Ernst, K. D. *et al.*, 1977; Ignell, R. *et al.*, 2001).

4.41.3.5.4 Humidity

Hygroreceptors are often found on insect antennae (Tominaga, Y. and Yokohari, F., 1982; Yokohari, F., *et al.*, 1982; Yokohari, F., 1983; Nishikawa, M. *et al.*, 1995; Shanbhag, S. R. *et al.*, 1995; Nishino, H. *et al.*, 2003; Tichy, H. 2007). Bees are known to control the humidity in their hives, and to carry water into the hive when they need it (von Frisch, K., 1966). The homeostatic nature of this water detection task makes it likely that humidity be coded in a nonadapting labeled line system, possibly with a single glomerulus. The function of this glomerulus would then be limited to integrating the signals from all hygroreceptors on the antenna, rather than taking part in across-glomeruli processing. However, experimental data do not support this view; bees can associate vapor with a sucrose reward, and reliably respond to it, just as they learn appetitive odors (Menzel, R., personal communication). In intracellular recordings from mlACT neurons, some PNs showed responses to water vapor, which was increased by association with sugar water (Abel, R., 1997). Therefore, the information channel for water must overlap with the circuits responsible for associative learning. No localization of the representation of humidity in the AL is possible from the data currently available, apart from some intracellular recordings of honeybee PNs that across the odors tested responded exclusively to vapor and branched in a glomerulus of the T2 tract (Müller, D., personal communication).

4.41.3.5.5 Other special odors

In ants, a sensillum that does not respond to nest mates but does respond to cuticular components of nonnest mates has recently been found (Ozaki, M. *et al.*, 2005). This sensillum contains about 200 OSNs. The projections of these OSNs are not known. Nestmate recognition is also found in honeybees, where guarding bees at the hive entrance attack approaching bees that do not have the nest's own cuticular odor (von Frisch, K., 1966). In Hymenoptera, this recognition relies on the mixture of hydro- carbons present on the animal's cuticle (Dani, F. R. *et al.*, 2005), which is often exploited by parasite species (Lenoir, A. *et al.*, 2001).

4.41.3.6 Effects of Memory

The AL is the first olfactory neuropil where substantial cellular interaction takes place. Some of that interaction is experience dependent. What, then, are the memory traces that can be found in the AL? Both nonassociative and associative effects have been found.

Nonassociative learning occurs as a consequence of odor exposure. When a locust is repeatedly exposed to an odor, odor responses in PNs change in a characteristic way: they have less APs, but these APs are more precisely timed, suggesting that odor coding is more efficient for the later puffs in the series (Stopfer, M. and Laurent, G., 1999). This sensory memory trace is already visible in the second and third puff and decays within 10–15 min after the last puff (Stopfer, M. and Laurent, G., 1999). A related effect was found in honeybees: even without an olfactory stimulus, PNs are spontaneously active, but there is no preferential pattern of activity. After a single odor exposure, however, a pattern corresponding to the experienced odor reoccurs repeatedly within the sequence of spontaneous events, showing that spontaneous activity within the AL network is temporarily biased toward this pattern (Galán, R. F. *et al.*, 2005).

Most studies investigating associative learning in the AL have looked at classical conditioning, in which an odor is associated with a punishment (e.g., electroshock and aversive learning) or a reward (e.g., sugar water and appetitive learning). In flies, after aversive conditioning, some glomeruli change their

odor responses for a short time window, that is, 3 min after conditioning (Yu, D. *et al.*, 2004). These experiments were done by optically measuring synaptic vesicle release within the AL using the reporter protein synaptopHluorin in the PN line GH146. Thus, the measurements monitored the feedback activity in PNs within the AL, in a population of mixed multiglomerular and uniglomerular PNs comprising approximately 60% of the total PN population.

Application of sucrose (or water) to the honeybee antenna elicits a transient increase of PKA activity in the AL, but odor stimulation alone does not (Hildebrandt, H. and Müller, U., 1995a; 1995b). This effect is mediated by octopamine and reverts to baseline within 3 s (Hildebrandt, H. and Müller, U., 1995b). The sugar water stimulus of the appetitive learning paradigm (the US) is also mediated by octopamine: it can be replaced by octopamine injections restricted to the AL (octopamine is the putative transmitter of VUMmx1, the neuron that mediates the US in the bee brain) (Hammer, M. and Menzel, R., 1998). Blocking octopaminergic transmission by injecting an octopamine receptor antagonist (mianserin) or by injecting double-stranded octopamine receptor RNA into the AL interferes both with odor memory acquisition and with its recall, suggesting that octopamine is important for memory consolidation but also that octopaminergic neurons become reactivated during memory recall (Farooqui, T. *et al.*, 2003). In honeybees, single-trial conditioning leads to short-term memory (STM), while multiple conditioning leads to LTM. In the AL, multiple conditioning trials lead to an elevated PKA response mediated by the NO/cGMP system. Artificially increasing PKA activity in the AL after single-trial learning elicits long-term memory (Müller, U., 2000), suggesting that the PKA level, rather than its presence alone, is important for a switch between STM and long-term memory. Bath application of a calcium-sensitive dye revealed an effect of differential conditioning (one odor was rewarded, the other not) in the time window of 5–15 min after conditioning, showing that learning modifies the odor representation in the AL (Faber, T. *et al.*, 1999). Similarly, extracellular recordings from moths showed a net recruitment of AL neurons activated by the rewarded odor and a net loss of neurons activated by the unrewarded odor (Daly, K. C. *et al.*, 2004).

Other studies have disputed the role of the AL in olfactory associative memory. In *Drosophila*, KCs have been shown to be necessary and sufficient for short-term learning of odors (see below), leaving no space for a memory trace in the AL (Gerber, B. *et al.*, 2004a). In honeybees, a subpopulation of PNs (the uniglomerular PNs from the lACT tract) have very stable odor responses that are not affected by single-odor training or differential appetitive training (Peele, P., *et al.*, 2006). These neurons might represent a learning-resistant channel for reliable transfer of odor-related information to higher-order brain centers.

Together, these studies show that odor learning in the AL is a complex process that might affect spike timing and/or relative activities to different odors. They also show that these effects only occur in very limited time windows and that not all cell populations are involved in these plastic processes.

Because the development of the olfactory system is not part of this review, developmental plasticity is also not treated, even though developmental experience does shape odor responses and AL morphology (Winnington, A. P. *et al.*, 1996; Sigg, D. *et al.*, 1997).

4.41.4 Cellular Organization of the Mushroom Bodies

Mushroom bodies (MBs) are multimodal structures and are involved in learning (Strausfeld, N. J. and Gilbert, C., 1992; Heisenberg, M., 2003; Davis, R. L., 2004). In most insects, they receive both olfactory and visual input (Strausfeld, N. J. *et al.*, 1998; Farris, S. M., 2005). MBs owe their names to massive peduncles with large cup-shaped protuberances, which are called the calyces.

4.41.4.1 Kenyon Cells

The intrinsic neurons in the MBs are the KCs. Their number differs widely among species: in honeybees, there are ~170 000 KCs in each hemisphere (Witthöft, W., 1967; Mobbs, P. G., 1982), and *Drosophila* counts give ~2500 KCs (Stocker, R. F., 1994). In adult cockroaches, the number is ~175 000 (Neder, R., 1959), but juveniles have much smaller numbers (Farris, S. M. and Strausfeld, N. J., 2001), and adult locusts have ~50 000 KCs (Farivar, S. S., 2005). KC somata are small and densely packed close to the MB calyces. Their axons are long and thin and form the peduncles. Most axons branch, so that the peduncle splits into two lobes: the vertical (α) lobe and the horizontal (β) lobe. In *Drosophila*, these lobes are accompanied by the α'- and the β'-lobes (Strausfeld, N. J. *et al.*, 2003). A third lobe, the γ-lobe, is morphologically distinct in *Drosophila*, but physically juxtaposed to the ventral

aspect of the vertical lobe (the α-lobe) in honeybees (Strausfeld, N. J., 2002; Farris, S. M. *et al.*, 2004). The γ-lobe is formed by axons of clawed KCs, which have been found in *Drosophila*, bees, and cockroaches (they are sometimes referred to as class II or type 5 KCs) (Mobbs, P. G., 1982; Rybak, J. and Menzel, R., 1993; Strausfeld, N. J., 2002; Farris, S. M. *et al.*, 2004). Their somata are located outside the calyx, unlike all other KCs that have their somata inside the calyces. The name clawed derives from the claw-like dendritic shapes within the calyces. These KCs are the first population to occur in development. While in a simplified view of the KCs, the calyces are the input region and the lobes the output region of these cells, input synapses are also found in the lobes, allowing for local feedback within the lobes (Strausfeld, N. J. *et al.*, 2003).

The calyces are subdividable: in hymenoptera, these subdivisions are lip, collar, and basal ring, which correspond to different layers in the lobes. In honeybees, KC from lip, collar, and basal ring project into three separate bands in the α-lobe (or vertical lobe). Similarly, in *Drosophila*, subdivisions from the calyces can be traced to a layered structure in the α'/β'-lobe, and to a concentrically circular arrangement in the α/β-lobe (Tanaka, N. K. *et al.*, 2004). These layers partially correspond to KCs that differ in their morphology and/or in what transmitters they use, or in other molecular markers. Glutamate has been found in a KC subpopulation of bees (Bicker, G. *et al.*, 1988). Aspartate, glutamate, and taurine immunocytochemistry leads to different KC populations being labeled in *Drosophila* (Strausfeld, N. J. *et al.*, 2003) and in cockroaches (Sinakevitch, I. *et al.*, 2001). In addition, in *Drosophila*, KCs produce NO (Schürmann, F. W., 2000), but ACh and GABA are excluded as KC transmitters (Yusuyama, K. *et al.*, 2002). The complexity in KC morphology, pharmacology, and peptide expression is considerable in all species studied so far (Iwasaki, M. *et al.*, 1999; Strausfeld, N. J. and Li, Y., 1999a; 1999b; Strausfeld, N. J. *et al.*, 2000; Sinakevitch, I. *et al.*, 2001; Strausfeld, N. J., 2002; Strausfeld, N. J. *et al.*, 2003).

4.41.4.2 Projection Neuron Input

Olfactory input to the MB calyces occurs via uniglomerular PNs. In honeybees, chemosensory input is targeted at the lip and the basal ring of the calyces, while the intermediate area, the collar, receives input from the optic lobes. Each of these input areas is further subdivided into segregated zones, suggesting the existence of several parallel channels (Gronenberg, W., 2001). Similar arrangements are also found in other hymenoptera (Gronenberg, W., 1999; 2001).

In *Drosophila*, each PN axon travels over large areas of the calyx, forming synapses with many intrinsic KCs (Marin, E. C. *et al.*, 2002; Wong, A. M. *et al.*, 2002). This is reminiscent of the situation in the mammalian olfactory cortex (Zou, Z. *et al.*, 2005) and allows for a combinatorial readout of PN response patterns. PNs within the MB calyx region occupy concentric layers (Tanaka, N. K. *et al.*, 2004). PNs from identified glomeruli branch in a stereotype manner within the MB calyces, and PNs from different glomeruli have distinct but overlapping branching patterns (Marin, E. C. *et al.*, 2002; Wong, A. M. *et al.*, 2002). On average, three uniglomerular PNs innervate each glomerulus, and these have the same projection pattern in MB and LP, suggesting that they are not functionally distinct (Wong, A. M. *et al.*, 2002). PNs with similar axon projection patterns in the LP tend to receive input from neighboring glomeruli in *Drosophila*, suggesting that the organization of the LP mirrors some aspects of the organization in the AL (Marin, E. C. *et al.*, 2002; Tanaka, N. K. *et al.*, 2004), but other studies have not found this relationship (Wong, A. M. *et al.*, 2002). However, whether such spatial correlations are dictated by developmental constraints or are the result of functional neuropil optimization, or both, remains to be investigated.

Schematically, MB input can be described as a scaffold, with arrays of PN axons running perpendicular to arrays of KCs, and forming synapses with some, but not all KCs (Heisenberg, M., 2003). This is an ideal arrangement for a combinatorial readout across PNs. In *Drosophila*, PN axons have large boutons, 2–7 µm in diameter, throughout all calycal subdivisions, which is a considerable size when compared to KC somata of about 4 µm (Yusuyama, K. *et al.*, 2002). PN boutons are multisynaptic, with GABAergic input and KC output connections arranged to form glomerular structures (see below). The detailed geometrical layout of this structure has led to comparisons with the mammalian cerebellum, where the GABAergic circuit in MBs would correspond to Golgi cells in the cerebellum (Yusuyama, K. *et al.*, 2002), but it is unclear whether this similarity includes the cerebellar specialization for precise AP timing. Others have likened the vertebrate cerebellum to the central complex, rather than to the mushroom bodies (Svidersky, V. L. and Plotnikova, S. I., 2004).

Although not all PNs may be cholinergic (see above), PNs are the only cholinergic input to the MBs in *Drosophila* (Yasuyama, K. and Salvaterra, P. M., 1999).

4.41.4.3 Local Inhibitory and Modulatory Neurons; Mushroom Body Glomeruli

Dense GABAergic processes invade the MBs (Yusuyama, K. *et al*., 2002). These synaptic arrangements form microglomeruli with very local computational capabilities. In *Drosophila*, each MB glomerulus comprises a large cholinergic bouton formed by a PN axon from the AL, which is surrounded by tiny vesicle-free KC dendrites and several GABAergic terminals (Yusuyama, K. *et al*., 2002). GABAergic terminals contact both KC dendrites and PN axon terminals, suggesting that PN input is modulated both pre- and postsynaptically (Yusuyama, K. *et al*., 2002). This electron microscopic arrangement is also found in bees (Ganeshina, O. and Menzel, R., 2001) and in locusts (Leitch, B. and Laurent, G., 1996). MB glomeruli have no glial sheath (Ganeshina, O. and Menzel, R., 2001; Yusuyama, K. *et al*., 2002). KC dendritic spines label for F-actin in all insects studied so far, while the PN terminal boutons do not (Frambach, I. *et al*., 2004). Physiological evidence for the functional role of this circuit is discussed below.

A second inhibitory circuit within the MBs consists of GABAergic feedback neurons from the MB lobes back onto their calyces (Bicker, G. *et al*., 1985). These neurons are few in number, in honeybees ~55. Each feedback neuron innervates a subcompartment in the calyx. Due to the arrangement of intrinsic KCs, each subcompartment in the calyx is connected to its specific, corresponding layer in the α-lobe (Grünewald, B., 1999b). These neurons are found in bees (Bicker, G. *et al*., 1985; Schäfer, S. and Bicker, G., 1986), moths (Homberg, U. and Hildebrand, J. G., 1994), *Drosophila* (Yusuyama, K. *et al*., 2002), cockroaches (Farris, S. M. and Strausfeld, N. J., 2001), and locusts (Leitch, B. and Laurent, G., 1996).

Octopaminergic cellular processes sparsely but uniformly innervate MB calyces (Strausfeld, N. J. *et al*., 2003). In honeybees, these are likely to be from the VUMmx1 neuron that represents the CS during olfactory learning (Hammer, M., 1997). VUMmx1 branches in the AL, the MB, and the LP and has been discussed in the Section 4.41.2.6.

4.41.4.4 Output Lobe Circuitry

In comparison with the many studies published about input connections to the MB calyces, about the internal organization between calyces and lobes, and about the feedback from the lobes back onto the calyces, what has been published about the MB output to the LP and other brain areas is little. These target areas probably include premotor areas, so that the loop OSN–AL–MB–LP–motor neuron may form a complete behaviorally significant neural control loop, paralleled by the direct AL–LP loop that bypasses the MBs. In the *Drosophila* brain, at least three areas are MB output regions: the superior medial protocerebrum, the inferior medial protocerebrum, and the superior lateral protocerebrum (Ito, K. *et al*., 1998; Tanaka, N. K. *et al*., 2004). However, the precise delimitations of these areas are still being worked out.

Honeybee MB output neurons include unilateral neurons as well as bilaterally innervating neurons (Rybak, J. and Menzel, R., 1993). A prominent large neuron in honeybee brains is PE1, which is a single neuron in each brain hemisphere and connects the α-lobe to the LP and the ring neuropil around the α-lobe (Rybak, J. and Menzel, R., 1998; Brandt, R. *et al*., 2005). Responses of this multimodal neuron are modified after olfactory learning (Mauelshagen, J., 1993).

4.41.5 Functional Organization of the Mushroom Bodies

4.41.5.1 Odor-Evoked Activity and Processing

There is a massive divergence between PNs and KCs. In honeybees, 800 PNs project onto 180 000 KCs, and this ratio is similar in other species. Patch-clamp recordings in locusts show that KC activity is rare as compared with PNs (Stopfer, M. *et al*., 2003): while PNs had a probability of $p = 0.64$ to respond to any of the tested panel of odors, KCs responded with $p = 0.11$ (Perez-Orive, J. *et al*., 2002). Furthermore, while PNs respond with trains of spikes, KCs often respond with single or very few spikes only. These results were confirmed in flies and honeybees using calcium imaging of PNs and KCs (Wang, Y. L. *et al*., 2004; Szyszka, P. *et al*., 2005). Thus, odor representation is sparse across KCs (Laurent, G., 2002), where sparse is used both as population sparseness (a low proportion of units active at any

time) and as lifetime sparseness (few spikes in each neuron with narrow tuning) (Olshausen, B. A. and Field, D. J., 2004). The transformation between PNs and KCs appears useful because it may facilitate the readout mechanism (Laurent, G., 2002) and may allow more efficient learning due to the perpendicular array structure between PNs and KCs, as noted above (Heisenberg, M., 2003).

A comparison of PN activity in the ALs with PN activity at the synaptic boutons in the MBs and with KC activity showed that this sparsening occurs progressively: activity trains arriving at the MB terminals are inhibited presynaptically within the MBs by GABAergic glomerular microcircuits, so that only the first APs are likely to drive activity in KCs (Szyszka, P. *et al.*, 2005). This mechanism implies that only the first activity wave of every odor response is relevant for decoding within the MBs. In addition, the inhibitory feedback loop from the MB output lobes onto the calyces further sharpens that response (Szyszka, P. *et al.*, 2005). This feedback loop also locks activity into a global oscillatory rhythm (Perez-Orive, J. *et al.*, 2002), which in turn favors the extraction of synchronized APs from PNs (Perez-Orive, J. *et al.*, 2004). In this framework, only spikes that are in phase with the oscillatory activity carry relevant olfactory information, and extracting them would reduce noise and optimize coding (Laurent, G., 2002).

4.41.5.2 Olfactory Coding

These studies result in two distinct models (that need not be entirely exclusive). In one, only the initial firing pattern is read out for each odor puff (Szyszka, P. *et al.*, 2005), in the other only APs in synchrony with oscillations are relevant (Laurent, G., 2002). In both, most APs of PNs are not involved in olfactory coding within the MB calyces. Therefore, the question arises whether the remaining APs are wasted. Given that firing APs is among the most energy-costly activities of the brain (Attwell, D. and Laughlin, S. B., 2001), such a waste would appear as quite inefficient. However, the surplus spikes may not be wasted at all: PNs make synaptic output not only in the MB but also within the AL and in the LP, and this output is not filtered by the MB circuitry. Therefore, APs that are ignored within the MBs could still be an important part for olfactory coding within the AL and the LP.

The olfactory system has been compared with a support vector machine (Galán, R. F. *et al.*, 2004). Assuming a simplified system that is based on a combinatorial readout without any time-dependent mechanisms, a recipient neuron that reads across PN activities can only perform a very limited classification, which statistically corresponds to a linear classification in a multidimensional space. However, the addition of the MB as an intermediate step changes this picture: with a relatively small number of PNs, combinatorially mapped onto a very large number of KCs, which then are combinatorially read out by very few recipient neurons, very complex pattern families can be extracted. The intermediate step of enormously expanding the number of units by a large number of KCs allows for the computation of highly nonlinear classification schemes across PNs, which is reminiscent of support vector machines (Huerta, R. *et al.*, 2004). By adding temporal complexity to the code, the theoretical capacity of the system increases even further (Laurent, G. *et al.*, 2001).

4.41.5.3 Effects of Memory

Early confirmation of the role that MBs play in olfactory memory came from cooling experiments in honeybees, where memory retrieval was impaired when the MBs were cooled (Erber, J. *et al.*, 1980). Similarly, *Drosophila* mutants where MB structure is altered (*MB deranged, mbd*, and *MB miniature, mbm*) have learning deficits (Heisenberg, M. *et al.*, 1985). When the MBs are chemically ablated by applying the DNA synthesis inhibitor hydroxyurea during the early proliferation phase of KCs, olfactory memory is impaired in *Drosophila* (de Belle, J. S. and Heisenberg, M., 1994). In honeybees, partial ablation of MBs does not impair easy learning tasks (Malun, D. *et al.*, 2002), but more complex tasks involving several odors are impaired (Komischke, B. *et al.*, 2005). Similarly, blocking synaptic activity or disrupting MB physiology also leads to memory deficits (Connolly, J. B. *et al.*, 1996; Dubnau, J. *et al.*, 2001; McGuire, S. E. *et al.*, 2001).

There are many olfactory tasks that do not require MBs, and indeed, fly mutants that lack MBs are remarkably normal: they court and copulate, feed, lay eggs, are alert, seem to be well oriented in space, and respond to odors (Heisenberg, M., 2003). Furthermore, MBs are necessary not only for olfactory tasks but also for spatial memory and navigation (Mizunami, M. *et al.*, 1998; Strausfeld, N. J. *et al.*, 1998; Kwon, H. W. *et al.*, 2004).

In honeybees, the VUMmx1 neuron that represents appetitive reinforcer also innervates the MB calyces, suggesting that coincidence detection for appetitive

olfactory learning in honeybees occurs in the MB input region (Menzel, R. and Giurfa, M., 2001), in contrast to findings from *Drosophila* (see below). Optical imaging experiments show that a rewarded odor leads to increased calcium responses in the MB calyces as compared to before learning (Faber, T. and Menzel, R., 2001). Experience leads to morphological changes in honeybee MBs: worker bees that forage have KC dendrites with more branches than age-matched bees that do not forage, while the density of dendritic spines remained constant (Farris, S. M. *et al.*, 2001).

The best mechanistical analysis of olfactory memory traces in MBs comes from *Drosophila* (Waddell, S. and Quinn, W. G., 2001; Dubnau, J. *et al.*, 2003; Heisenberg, M., 2003; Davis, R. L., 2004). Olfactory memory can be subdivided into at least four phases: STM decays within an hour, middle-term memory (MTM) within 3 h, while anesthesia-resistant memory (ARM) and long-term memory (LTM) are two forms of LTM that differ in their training procedures: ARM occurs after massed training, and the protein synthesis-dependent LTM occurs after spaced training, that is, a training protocol where individual learning events occur with longer intervals in between (Tully, T. *et al.*, 1994).

Based on our current knowledge, KCs are the cells where this memory is located (Gerber, B. *et al.*, 2004a). A necessary second messenger in STM is cyclic AMP, and mutants for the genes *dunce* (*dnc*, which is a cAMP phosphodiesterase), DC0 (which is a PKA catalytic subunit), or CREB (cAMP response element binding protein) all are impaired in memory tasks. The *Drosophila* gene *rutabaga* (*rut*) codes for a Ca/CaM-dependent adenylyl cyclase (Levin, L. R. *et al.*, 1992). When *rut* is mutated, olfactory learning is impaired, but when *rut* is expressed in a mutant background in MB cells only, learning is restored (Zars, T. *et al.*, 2000). Several lines were used in these experiments, and the clawed KCs were the set of cells common to all of the effective lines, suggesting that clawed KCs are sufficient for short-term olfactory learning. A selective loss-of-function study of these cells showed that they are also necessary for olfactory learning (Connolly, J. B. *et al.*, 1996). The function of *rut* is only necessary in adult animals, but not during development (McGuire, S. E. *et al.*, 2003; Mao, Z. *et al.*, 2004). Furthermore, it acts presynaptically at the output synapses of KCs, and blocking synaptic release of these cells impairs retrieval, but not acquisition (Dubnau, J. *et al.*, 2001; Schwaerzel, M. *et al.*, 2002).

The gene *amnesiac* (*amn*) is strongly expressed in two large neurons, the two dorsal paired medial (DPM) neurons, and codes for a neuropeptide PACAP (pituitary adenylate cyclase activating peptide) that modulates *rut* activity in KCs. Disruption of *amn* leads to loss of MTM, as does silencing of DPM neurons. For the odors octanol and methylcyclohexanol, DPM neuron activity is necessary during storage and possibly consolidation, but not during acquisition and recall. However, memories for benzaldehyde need DPM neuron activity during acquisition (Keene, A. C. *et al.*, 2004). These data show that olfactory memory is not only highly complex in terms of memory phases and neural and genetic networks, but also diverse with respect to the odors used, adding tremendous complexity to the system.

The MBs are also involved in the two forms of long-term memory, ARM and LTM. These memory stages are not sequential: ARM is formed even in *amn* mutants that show no MTM and at least partially also in *rut* mutants that show no STM (Isabel, G. *et al.*, 2004). STM/MTM and ARM/LTM possibly rely on different KC populations, that is, those from the γ-lobe and from the α/β-lobe, respectively (Zars, T. *et al.*, 2000; Pascual, A. and Preat, T., 2001; Isabel, G. *et al.*, 2004). Nevertheless, LTM and ARM are not independent pathways: rather, LTM leads to an active erasure of ARM memory (Isabel, G. *et al.*, 2004). The cAMP response element CREB appears to be related to LTM (Yin, J. C. and Tully, T., 1996), although the scientific evidence has recently been questioned (Perazzona, B. *et al.*, 2004).

Associative learning occurs when a CS (which in this case is an odor) is paired with a US in a way that the CS acts as an efficient predictor for the US. A positive reward as US, such as food, elicits an appetitive response, while a negative US, such as an electric shock, leads to aversive conditioning. The sensory input for the US and the behavioral responses of these two paradigms are clearly distinct. Therefore, the neuronal pathways should be different. Indeed, in *Drosophila* an appetitive US is mediated by octopaminergic neurons, while an aversive US is mediated by dopaminergic neurons (Schwaerzel, M. *et al.*, 2003). This is consistent with findings in honeybees, where appetitive learning is mediated by octopamine (Hammer, M. and Menzel, R., 1998).

4.41.6 Cellular and Functional Organization of the Lateral Protocerebrum

In insect olfaction, the LP is, unfortunately, the least studied area. A frequent belief is that this area is

more related to innate behavior control, and less plastic than the circuitry in the MBs (Tanaka, N. K. *et al.*, 2004). Several lines of evidence support this model: in *Drosophila*, individual PNs branch in a highly stereotype and genetically predetermined way in the LP, while their branching pattern in the MBs is less predictable (Marin, E. C. *et al.*, 2002), and animals with ablated MBs but intact LP are not impaired in innate odor responses (de Belle, J. S. and Heisenberg, M., 1994). Because LP areas inherit the plasticity that comes from plastic MB output neurons such as the PE1 neuron (Mauelshagen, J., 1993) and the PCT neurons in honeybees (Grünewald, B., 1999a), local circuits involved in learning are more difficult to identify. Within the LP, there are many subregions that receive olfactory information, some from the AL only, and some from both the AL and the MB (Ito, K. *et al.*, 1998; Tanaka, N. K. *et al.*, 2004). Furthermore, the ring neuropil surrounding the vertical lobe is densely innervated by olfactory neurons.

4.41.7 The Larval System

This review focuses on the olfactory system of adult insects. The larval system has recently started to receive closer attention (Cobb, M., 1999; Heimbeck, G. *et al.*, 1999; Stocker, R. F., 2001; Scherer, S. *et al.*, 2003; Kreher, S. A. *et al.*, 2005; Marin, E. C. *et al.*, 2005). Most importantly, the larval system is much simpler than the adult, in terms of both cell numbers and organization, but shares important principles of the adult (Python, F. and Stocker, R. F., 2002a; 2002b). Larvae are suited for complex behavioral assays, including learning experiments (Scherer, S. *et al.*, 2003; Gerber, B. *et al.*, 2004b; Hendel, T. *et al.*, 2005). OSN afferents to the larval AL also form glomeruli that are interconnected by LNs, even though each glomerulus only receives input from a single OSN axon and is innervated only by a single PN (Kreher, S. A. *et al.*, 2005; Ramaekers, A. *et al.*, 2005). In *Drosophila* larvae, there are about 21 OSNs and about 25 expressed OR genes, of which only 13 are expressed in adults (Kreher, S. A. *et al.*, 2005; Ramaekers, A. *et al.*, 2005). That indicates that the different environment to which the larva is adapted has led to evolving a dedicated chemosensory system. This is further substantiated by the larger number of gustatory neurons in larvae than in adults. The larval mushroom bodies also share many of the characteristics with its adult counterpart (Marin, E. C. *et al.*, 2005). Given its numerical simplicity, it is easy to predict that we will learn a lot more about the larval olfactory system in the near future.

4.41.8 Olfactory Behavior

Theodosius Dobzhansky (1900–1975) stated, "Nothing in biology makes sense except in the light of evolution." For the individual animal, this can be paraphrased to behavior, and the statement becomes even more relevant for the scientific approach to studying olfaction, because it is only through observing behavior that it is possible to judge and investigate how an animal is making use of olfactory cues.

Olfactory behavior in insects has been studied in many species. An extensive review is beyond the scope of this chapter. Therefore, I limit myself to list some types of behavior that impose different constraints and/or requirements onto olfactory processing. Generally, insects are considered as more genetically predetermined and less plastic in their behavior than mammals. However, there are some olfactory behaviors that are exquisitely plastic, and even cognitive capabilities can be found in insects.

4.41.8.1 Odor Learning

Olfactory learning in insects has been reviewed extensively (Menzel, R. and Müller, U., 1996; Dubnau, J. *et al.*, 2003; Giurfa, M., 2003a; Heisenberg, M., 2003; Davis, R. L., 2004; Gerber, B. *et al.*, 2004a; Giurfa, M. and Malun, D., 2004), having been studied in many insects, notably honeybees (von Frisch, K., 1966; Menzel, R. and Müller, U., 1996), bumblebees (Plowright, R. C. and Laverty, T. M., 1984), moths (Fan, R. J. *et al.*, 1997; Hartlieb, E. *et al.*, 1999; Daly, K. C. and Smith, B. H., 2000), cockroaches (Sakura, M. *et al.*, 2002; Watanabe, H. *et al.*, 2003), and crickets (Matsumoto, Y. and Mizunami, M., 2004). No olfactory learning studies with locusts have yet been published, although non-olfactory learning capacities have been shown in *Schistocerca* (Dukas, R. and Bernays, E. A., 2000). Interestingly, also animals for which the ecological relevance of learning is not fully understood can be trained, and the most important example of this category is appetitive learning in the fruit fly, *Drosophila*, which can be trained both as adult (Borst, A., 1983; Schwaerzel, M. *et al.*, 2003) and as larva (Scherer, S. *et al.*, 2003; Hendel, T. *et al.*, 2005).

The most powerful approach to study olfactory learning relies on classical conditioning, by pairing a US with an odor as CS. Appetitive training is commonly used in bees, and sugar water (as nectar surrogate) is used as US. Most (but not all) studies in *Drosophila* use aversive learning with electroshocks as US. At a cellular level, appetitive and aversive pathways are different (see above) (Schwaerzel, M. *et al*., 2003). Decay of memory over time appears as seamless. However, this is the result of overlapping distinct memory phases (ATM, MTM, ARM, and LTM, in *Drosophila*), which can be induced by different training protocols (massed versus spaced training, and/or number of trials), and which rely on different cellular mechanisms (transcription, translation only, and phosphorylation only, see above). For example, long-term memory depends on a distributed arrangement of repeated conditioning trials over time (spaced training), whereas the same number of conditioning trials induces STM if applied in rapid succession (i.e., massed training) (Tully, T. *et al*., 1994).

Classical conditioning experiments in insects show all characteristics studied in psychological learning theory: the CS and the US have to coincide within a critical time interval, and the CS has to precede the US (Sutton, R. S. and Barto, A. G., 1981; Giurfa, M., 2003b). Protocols investigating blocking, latent inhibition, negative patterning, and positive patterning all work in honeybees, and complex training protocols reveal that honeybees have almost cognitive capacities (Menzel, R. and Giurfa, M., 1999; Giurfa, M., 2003a), including the capacity to discriminate between 'same' and 'different' and to transfer this concept between the visual and the olfactory system (Giurfa, M. *et al*., 2001).

4.41.8.2 Attractive and Repulsive Odors

In appetitive training experiments in bees, not all odors are equally easy to learn, suggesting that some odors have an innate bias toward being attractive (Vareschi, E., 1971). Similarly, in *Drosophila*, some odors are attractive and others repellent, but almost all odors are repellent when tested at very high concentrations (Borst, A., 1983).

In some cases, adding a component to a mixture can create a repellent effect. For example, the commercially used substance *N*,*N*-diethyltoluamide (DEET) acts as a repellent for many insects including mosquitoes (Rutledge, L. C. *et al*., 1978). The mechanistic explanation for its activity is still missing. Its effect on many species would suggest that it acts physiologically on olfactory mechanisms rather than interfering with a behavioral pattern. In other cases, specialized communication channels can be disrupted by added odors, such as when additional substances are added to a sexual pheromone. For example, sympatric moth species often use similar substances in their sexual pheromone blends, and a small amount of a substance belonging to a sympatric species can already block the attractive action of a pheromone (Vickers, N. J. and Baker, T. C., 1997). Interestingly, adding such a behavioral antagonist to the environment has been tested as one means for mating disruption in pest control, but the effects are limited, suggesting that the plume structure from an individual source can be recognized even against the repellent signal from another source (Cardé, R. T. and Minks, A. K., 1995).

4.41.8.3 Social Communication – Pheromones

Social insects have a large number of olfactory-guided behaviors, many of which are controlled by pheromones. Honeybees use social pheromones such as aggregation pheromones and alarm pheromones, among others. Processing of these odors in the AL is treated above. The behavior elicited by social pheromones is a stereotypical and innate behavior. However, the behavior is not conditional on the odor only: individuals are receptive or not, depending on the circumstances. This is true both for the released pheromone itself, which can elicit different behaviors in different hive situations (e.g., for a stable hive, or when a hive is swarming), and for a chemical component (e.g., isoamyl acetate, which is a component of the alarm pheromone but does not elicit defensive behavior when it is the component of a flower odor). Whether these differences in elicited behavior are controlled within the olfactory system (e.g., by feedback neurons), or in multimodal brain centers, is unknown.

Social pheromones have been studied particularly well in ants (Hölldobler, B. and Wilson, E. O., 1990). Some pheromones have different behavioral effects with increasing distance from the releasing individual, either due to decreased odor concentration or because in a mixture different volatilities of the components lead to changing component ratios with increasing distances, thus creating unique odor fingerprints for distance. For example, the alarm secretion of the ant *Oecophylla longinoda* contains

several substances that are active in concentric circles: 2-butyl-2-octenal in the inner circle elicits biting, 2-undecanone in the next elicits attraction and biting, 1-hexanol in the third elicits attraction, while the fourth concentric circle, 1-hexanol, only elicits attraction – all circles together having a radius of <10 cm (Hölldobler, B. and Wilson, E. O., 1990). Such a separation of mixture components is only possible because, physically, the aerodynamics of an ant's olfactory environment is different from that of a flying insect: in the air layer immediately above ground, turbulence is almost irrelevant, and odor diffusion becomes dominant. Tropotaxis is common, that is, ants follow odor concentration gradients, and they compare bilateral olfactory input from their antennae. The olfactory environment of a cockroach is also a substrate-bound still-air environment, and much behavior is related to active antennal movement. Spatial sampling of the olfactory environment is common in cockroaches (Boeckh, J. and Tolbert, L. P., 1993). However, even flying insects such as *Drosophila* are capable of using concentration differences between the two antennae for orientation (Borst, A., 1983), although the ecological relevance of this behavior has not yet been analyzed.

4.41.8.4 Sexual Communication – Pheromones

Sexual pheromone-related behavior (best studied in moths) is fundamentally different. These free-flying animals follow pheromone plumes that are transported downwind over large distances. The nature of the trail is inherently turbulent (Murlis, J. *et al.*, 1992). Odor concentration varies greatly, but the relative ratio of pheromone components does not. Consequently, the olfactory system is optimized to recognize a particular, genetically determined blend of substances, and male moth ALs have a stereotypical macroglomerular complex with glomeruli specifically dedicated to their species' pheromone components and to behavioral antagonists, which often are pheromones of closely related, sympatric species. Moths do not follow concentration gradients of pheromones. Rather, when they encounter an odor plume, they fly upwind, and when contact with the pheromone stops, they fly sideways (casting behavior) (Willis, M. A. and Baker, T. C., 1984; Cardé, R. T., 1996). In other words, the odor gives the information of when to fly, and the wind gives the information of where to fly. Therefore, the olfactory system is optimized for detecting short bursts of odors, with high frequencies (Christensen, T. A. and Sorensen, P. W., 1996). These mechanisms are not universal: some moths, such as storage pests that live in enclosed environments, have lost the requirement for turbulent pheromone trails (Justus, K. A. *et al.*, 2005).

Some plants, notably orchids, have evolved the capacity to mimic sexual pheromones and attract insects to pseudocopulate with them, thus insuring pollination (Schiestl, F. P. *et al.*, 2000; Ayasse, M. *et al.*, 2003).

4.41.8.5 Navigation – Innate Odors

Navigation toward an odor source occurs not only in the context of sexual calling but also in other behavioral contexts, for example in food source finding. Innate odors that are used for navigation are likely to rely on genetically encoded, hardwired olfactory coding mechanisms. Alternative models are also possible, such as early olfactory imprinting, in particular for phytophagous insects where the feeding substrate of a larva might influence the olfactory preference of the ovipositioning adult female.

Female moths follow characteristic odor trails of their host plants for finding good oviposition sites. Possibly, the neural circuits responsible for this are related to those of the male moth finding the female pheromone trail, as suggested by cross-grafting of female antennae onto male moths and vice versa (Schneiderman, A. M. *et al.*, 1986; Rössler, W. *et al.*, 1999a). Plants produce the attractive odors. They are often part of their obligate metabolic processes, which means that they represent evolutionarily reliable signals. Plant odor preferences can cause sympatric speciation, as shown in *Rhagoletis* flies, where two hosts (apple and hawthorn) are visited by different fly populations that prefer the respective plant odor substances (Linn, C. *et al.*, 2003; Linn, C. E. *et al.*, 2004).

Some plants respond to insect challenge by releasing stress volatiles, which act as attractants for other insect species that parasitize on the phytophagous species, creating tritrophic interaction systems (Karban, R. and Baldwin, I. T., 1997; Pare, P. W. and Tumlinson, J. H., 1999). Olfactory orientation of the parasitoids themselves consists in being attracted to an innately attractive odor.

Mosquitoes find their blood meals following a combination of cues, including lactic acid, ammonia, and CO_2, which act synergistically (Kline, D. L., 1998; Geier, M. *et al.*, 1999a; 1999b; Costantini, C. *et al.*, 2001; Steib, B. M. *et al.*, 2001; Dekker, T. *et al.*, 2002; Dekker, T. *et al.*, 2005). Such synergistic effects

are caused by mixture interactions, but it remains to be elucidated where within the olfactory pathway these interactions occur. Interestingly, humans that are infected with malaria gametocytes (the transmissible stage) are particularly attractive for the mosquito vector *Anopheles gambiae*, suggesting that the parasite might induce a change in the olfactory signature of the human host (Lacroix, R. *et al.*, 2005).

Insects feeding on carrion (e.g., blowflies) are also attracted by specific, innate odor cues, which often act synergistically with other sensory cues, such as heat or color. Some flowers have evolved appropriate displays to mimic these signals and use carrion-feeding insects as pollinators (Angioy, A. M. *et al.*, 2004; Raguso, R. A., 2004).

Navigation for innate odors includes trail pheromone navigation, used in many ant species (Hölldobler, B. and Wilson, E. O., 1990).

4.41.8.6 Navigation – Learned Odors

Not all odors used for navigation are innate. Many pollinating insects learn which flower is currently in blossom and use this information to improve their foraging success. When an odor trail is used for navigation in these instances, the brain cannot rely on innate circuitry. Whether the behavioral strategies and the neural circuitries for finding the odor source are comparable with those used for innate odors is currently unknown.

Odors are not the only cues used for navigation. Bees learn both olfactory and visual elements of a flower. However, optical resolution is low, and odors are the only long-range signals that are available for a bee. The optical resolution of a bee allows to see an inflorescence of 8 cm at a distance of ~90 cm and to recognize its color at a distance of ~30 cm, leaving olfaction alone for everything farther away than 90 cm (Galizia, C. G. *et al.*, 2005). Honeybees also use their topographical knowledge of the landscape for navigating (Giurfa, M. and Capaldi, E. A., 1999; Menzel, R. *et al.*, 2000). Scout bees communicate the location of a new crop using the waggle dance (von Frisch, K., 1966). But even during the waggle dance, follower bees experience the flower's odor on the dancer's body and might use that odor as an additional clue for navigation. This has led to a long controversy among bee researchers, with some researchers advocating odors as the main navigation clue opposed to those arguing for the dominant role of the bees' waggle dances (Wenner, A. M. and Johnson, D. L., 1967; Wenner, A. M., 2002). Recent studies that monitored individual bees' flights after receiving information from recruiter bees have shown that the waggle dance is the dominant information used (Riley, J. R. *et al.*, 2005).

Some orchids mimic a rewarding flower. This situation is quite different from sexual pheromone mimicry, because flower odors consist in more complex mixtures than pheromones, and therefore, their reproduction by a deceiving plant may be biochemically more difficult. In at least one of these cases, the mimicry only involves visual parameters, while the long-range task of attracting pollinating bees is solved not by mimicry but by having a model inflorescence in close neighborhood (Galizia, C. G. *et al.*, 2005). In other words, these orchids hitchhike on their model's olfactory display and attract the pollinators at close range with their visual display only.

4.41.9 Limitations and Potential of Using Insects to Study Olfactory Coding

Some people argue that it becomes increasingly difficult to justify research in insect olfaction. The classical advantages of insect models are the limited number of neurons and even more so the possibility of identifying individual neurons, thus allowing for detailed analyses across animals. With the recent technological advances in mammals, both in recording techniques and in molecular and genetic manipulations, these advantages lose in importance: insects no longer are the simpler models for mammalian neurophysiological research.

However, insects remain important models on their own. The relative simplicity of their brains makes it possible to study many species in great detail and thus to understand not just one solution that evolution proposed for olfactory coding, but several solutions. This comparative approach is the main treasure that insect studies can contribute. However, it comes with a price, and the consequences of this price weaken the case for studying insect olfaction: because technical approaches and possibilities differ in different laboratories and species, our information is often insufficient for a thorough comparison among species. For example, as stated above, temporal aspects of odor responses in PNs are best studied in locusts, while across-PN patterns are best understood in honeybees and flies, with moths somewhere in between. This fragmentation of knowledge and research time severely limits

the conclusions that can be drawn, in particular with respect to understanding which mechanisms are universal and which are specific specializations. The massive advance in possibilities provided by molecular biology in *Drosophila*, and the concomitant increase in laboratories involved in studying fly olfaction, will help by creating a well-understood insect model species. However, it is important to realize that *Drosophila*, just as any other insect species, is not a good model for insect olfaction. The diversity among insects is enormous, and it is this treasure that we need to unearth for our understanding of the basic mechanisms in olfaction.
